more improvement on the MEPS measure than would the control group. This was expected, since the MEPS instrument is designed to measure interpersonal problem-solving skills and only treatment subjects participated in group sessions specifically designed to increase these skills. Table 1 presents the means and standard deviations for the various criteria on which the subjects' stories were scored. First, the two groups were compared with respect to the number of relevant means that they generated for the five MEPS stories that were administered as pretests and posttests. An examination of the difference scores (difference = number of posttest means minus number of pretest means) for the two groups shows that the treatment group made significantly greater improvement than did the control group, $t(54) = -3.32$, $p < .002$. Even though the two groups performed approximately the same on the pretest (control = 5.96 means, treatment = 5.77 means), the treatment group generated far more means than did the controls on the posttest (controls = 5.85 means, treatment = 9.27 means).

An examination of the scores obtained by the treatment and control groups on the individual MEPS stories for the posttest demonstrated that the significant overall differences were not accounted for by any one story or by only a few stories. In fact, the average number of means generated by the treatment group was greater than that of the control group for each of the 10 stories that comprise the MEPS procedure.

Mean relevancy scores for the treatment and

control groups are also presented in Table 1. The relevancy score was obtained by dividing the number of relevant means generated by the total of all the means generated for each subject. The relevancy score is an index of the extent to which subjects in the two groups responded with relevant and effective solutions to the MEPS stories administered. Although the treatment group showed more positive change in the relevancy score from pretesting to posttesting than did the control group, this difference did not reach statistical significance, $t(54) = .24$, $p < .24$. That the treatment group increased their relevancy score from .76 to .91, whereas controls increased merely from .69 to .75, however, suggests that there is a strong trend that favors the treatment subjects in the predicted direction.

In addition to the comparisons between the two groups on the basis of number and relevancy of means generated, Table 1 also presents a comparison of the groups with respect to other story elements including enumerations (elaborations) of means, obstacles, and the acknowledgment of passed time. The control and treatment groups did not differ significantly on any of these measures. However, the treatment group tended to perform better on each of these dimensions than did the control group of the posttest protocols.

Discharge interview. Performance in the interview was analyzed by means of a 2×2 analysis of variance (control/treatment vs. prepared for interview/unprepared). The results of this analysis are presented in Table 2. These results demonstrated a highly significant main effect due to group membership, $F(1, 59) = 10.2$, $p < .003$, no main effect resulting from differences in preparation for the interview, $F(1, 59) = .002$, $p < .99$, and no significant interaction between group membership and interview preparation $F(1, 59) = 1.0$, $p < .99$.

Table 3 presents the actual means and standard deviations of interview scores for both the treatment and control groups. This table demonstrates that the significant difference between the two groups in the interview was not a result of one question or a specific subset of questions. Rather, the treatment group performed better on all dimensions of the interview.

Though the interview was highly structured, it seemed important to monitor whether the group therapists administered it to both control and treatment subjects in a substantially similar manner. To check this, four of each therapist's discharge interviews were randomly selected for analysis (two interviews of control subjects, two of treatment subjects). Since there were four therapists, this meant that a total of eight interviews were selected from both the control and treatment groups. These interviews of control and treatment groups were compared on each of the following variables for both interviewers and interviewees: (a) number of responses, (b) length of responses (in seconds), and (c) total time taken for the interview. There were no significant differences between interviews of control and treatment subjects for any of the indices examined.

Discussion

The results of Study 1 provide further evidence of the content and concurrent validity

of the MEPS measure. First, MEPS scores were found to be significantly related to the social competency of the alcoholic subjects in the study sample. Further, the MEPS scores were also found to be significantly related to subjects' performance in an interview designed to assess the quality of their planning for dealing with postdischarge problems.

As in previous work reported by Platt and Spivack (1975), the correlation between the MEPS scores and IQ measures reached significance, though it was of a magnitude suggesting that the MEPS is not merely another IQ test. However, unlike the study reported by Platt and Spivack (1972b) in which partialing IQ out of the correlation between MEPS and social competency scores strengthened the relationship, the same partialing procedure in this study significantly weakened the relationship between the two measures. One possible explanation for this discrepancy is that in the Platt and Spivack (1972b) study, the index of IQ was a comprehensive full scale score. In the present study, a scaled vocabulary score

alone was the index of subjects' IQ. Thus, the subjects' verbal skills, and not their general intellectual ability, was the factor that was partialled out. Since the MEPS is a measure of cognitive ability heavily dependent on a subject's ability to verbalize problem-solving thoughts, it is not surprising that the partialing out procedure had a more significant impact in this study.

Finally, Study 1 explored, for the first time, the impact of a problem-solving skills training program on the relationship between the MEPS measure and an index of intellectual ability. The results suggest that the extent to which a subject's score on the MEPS procedure is dependent on verbal skills *decreases* following problem-solving training. Though training did not increase the participants' verbal proficiency, it apparently changed the way in which they used whatever verbal skills they already possessed. Thus, they were able to conceptualize qualitatively better solutions to the real-life problems presented to them in the final MEPS administration than they had prior to training. This is an exciting discovery because it suggests that individuals with even limited verbal skills can learn a more effective cognitive strategy for approaching everyday problems.

Study 2 demonstrated that 10 structured group sessions focusing on the processes of effective interpersonal problem solving were sufficient to result in the treatment group showing significantly more improvement, relative to controls, on the MEPS measure of interpersonal problem-solving thought. A closer look at the specific nature of this greater improvement revealed that the thinking of treatment subjects improved qualitatively as well as quantitatively. On the posttest, treatment subjects generated stories that were longer and contained significantly more effective problem-solving means than those generated by controls. In addition, the proportion of the means generated that were judged to be relevant and effective responses was substantially greater for the treatment group than it was for the control group.

Treatment subjects, however, not only performed better on a paper-and-pencil measure of problem-solving thought, but they also utilized their improved problem-solving think-

ing to produce qualitatively better plans for dealing with postdischarge problems than did controls. In the structured discharge interview, treatment subjects demonstrated that the positive gains they had made following problem-solving training generalized successfully at least to an in-hospital situation in which they were asked to confront real-life problems.

The population of alcoholic subjects in this study demonstrated a significant deficiency in interpersonal problem-solving skills when compared to the MEPS norms for a normal adult population provided by Platt and Spivack (1975). As discussed previously, Platt (Note 2) identified a population of heroin addicts as similarly deficient (relative to normals) in these same cognitive skills. Together these findings suggest that drug-addict populations may, in general, be very appropriate targets for problem-solving skills training. More importantly, the generally positive results of such training reported by Platt (Note 2) and in the present studies provide encouragement that such problem-solving skill deficiencies may be amenable to positive change. Future research in this area, however, must do more than explore the feasibility and potential effectiveness of problem-solving training with addict populations. Studies must attempt to demonstrate that this intervention approach can lead to significant positive behavioral change after subjects have returned to the community. Designs that include plans for moderate and long-term follow-up of subjects are essential.

The design of the present study included only a modest follow-up component. Treatment subjects were contacted 1 month following their discharge to determine how well they remembered the problem-solving principles that they were taught and whether or not they had made use of these principles in dealing with real-life problems. Although the majority of those contacted (14/22) reported having made practical use of the principles, it was evident that subjects had already forgotten significant portions of the training material. Thus, if more rigorous follow-up efforts are to be conducted in the future, it would seem reasonable to also explore the utility of occasional "refresher" sessions for the subjects receiving problem-solving training. In addi-

tion, to increase the likelihood of long-term impact, it would seem essential to integrate interpersonal problem-solving principles and concepts into all the components of a comprehensive treatment program rather than to artificially restrict problem-solving training to 10 special sessions as was done in the present study.

Certainly the use of problem-solving skills training ought not to be restricted to addict populations. Siegel and Spivack (1973), for example, reported encouraging results with pilot efforts to use such training with chronic schizophrenics. Platt (Note 3) reported that he was aware of some encouraging pilot work using cognitive problem-solving skills training with the mentally retarded. In addition, D'Zurilla and Goldfried (1971) reported that informal clinical experimentation and pilot work with college freshmen suggested that teaching a general cognitive approach to solving real-life problems seemed to be a promising conceptual strategy in aiding these individuals in coping with the transitions to college living.

In selecting populations and designing programs to improve cognitive interpersonal problem-solving skills, however, a number of factors that can affect the outcome of these interventions should be considered. One such factor may be the verbal skills of the participants. It seems reasonable to assert that a certain minimal level of verbal skill is essential for the cognitive training approach to have a significant impact. This assertion is supported, in part, by the results of this study. Although the majority of those contacted in the follow-up reported having made use of the training in real-life problem situations, it was the more verbally skilled subjects who reported having made greatest use of the training principles since leaving the hospital. Thus, although training may have had a significant immediate impact on the treatment group as a whole, the retention and use of the principles taught may be dependent on the level of the subjects' verbal skills. Other important factors that should be considered include the participant's level of social competence; use of the training intervention as an adjunct therapy (as in this study) versus its use as a solo intervention;

and the number, length, and sequencing of training sessions.

Spivack (1973) proposed that healthy psychological functioning is, in large part, dependent on the ability to cope effectively with the demands of problematic life situations. To deal effectively with such demands, an individual must be able to respond in a competent manner both cognitively and behaviorally. That is, a person must be able to decide what is the best way to cope with the problem as well as be able to actually perform the chosen behavior. The treatment intervention used in this study attempted to provide participants with an opportunity to learn and practice both cognitive and overt behavioral problem-solving skills. The focus of the training sessions, however, was clearly to teach participants a cognitive strategy for dealing constructively with all sorts of problems regardless of their specific content. Thus, general cognitive style rather than specific behavioral skills was emphasized. Though this particular emphasis led to desirable consequences for the subjects in this study, other populations may receive more benefits from training programs that focus more on teaching specific effective behaviors for specific types of real-life problems. For example, Argyle, Trower, and Bryant (1974) reported that they have taken the more specific behavioral approach in their work with neurotic psychiatric patients. Further research must be done to determine which syntheses of cognitive and behavioral skills training are most effective for specific problem populations.

Summary

These studies demonstrated three key points: (a) Problem-solving thinking skill is related significantly to social competency and to "planning ahead for problems" behavior in an alcoholic population, (b) problem-solving thinking skills (as measured by MEPS) of adult alcoholics can be improved significantly through the use of structured training sessions, and (c) improved problem-solving thinking is generalized by subjects from the training sessions into real-life problem situations both within the hospital and after their discharge.

Anxiety during the stressful medical procedure of endoscopy was studied as a function of the number of prior viewings of an explicit preparation videotape and of repression-sensitization coping style. Sixty naive patients viewed a videotaped endoscopy either zero, one, or three times. Dependent measures included heart rate, behavioral ratings, tranquilizer required, and self-report. On each dependent measure, three viewings generally resulted in the least distress; one, more distress; and zero, the most distress. Most comparisons reached statistical significance. These results are interpreted as resulting from extinction and/or habituation of anxiety. The repression-sensitization factor interacted with heart rate change. Sensitizers showed a monotonic decrease in heart rate as a function of number of tape exposures. Repressors showed an inverted-U-shaped function, with one viewing producing the highest heart rate; this is interpreted as resulting from a disruption of repressing defenses by one tape exposure followed by extinction of fear by three exposures.

Preparation-for-stress messages have generally proved effective in reducing the emotional trauma of stressful real-life experiences (e.g., Cassell, 1965; Janis, 1958; Johnson & Leventhal, 1974; Vernon & Bailey, 1974). The content, emphasis, and medium of the preparation messages have varied greatly, but most are based on the modeling and/or accurate information theories.

Modeling of approach responses has been effective in reducing phobic fear and avoidance

(Bandura & Menlove, 1968). Viewing of models who are initially fearful and who then overcome their fear ("coping model") has been found to be more effective than the viewing of models who are fearless throughout the stressful event (Kazdin, 1974; Meichenbaum, 1971; Vernon, 1974). Melamed and Siegel (1975) found that children who viewed a coping model were subsequently less anxious before and after surgery than children who viewed an unrelated control film.

Preliminary results of this study were reported at the convention of the Association for the Advancement of Behavior Therapy, New York City, December 1976.

The authors wish to acknowledge the help of the professional staff of the Division of Gastroenterology, Department of Medicine, University of Missouri, and the staff of the Medical Media Production Service, Harry S. Truman Memorial Veterans Hospital. Appreciation is also given to Ellen Horwitz and Dennis McGuire for critical readings of the manuscript.

Requests for reprints should be sent to Robert H. Shipley, who is now at the Veterans Administration Hospital, Fulton Street and Erwin Road, Durham, North Carolina 27705.

A second theory of preparation effects focuses on the formation of accurate cognitive expectancies. Emotional distress during a stressful event is thought to be caused by a discrepancy between current experience and prior expectation (Hebb, 1946; Johnson, 1973; McClelland, 1951). Preparation-for-stress messages based on this theory attempt to provide the information necessary for the subject to form accurate expectancies regarding the stressor and their reaction to it (e.g., Johnson & Leventhal, 1974).

The present study used a stressful medical

examination to investigate a third variable: the amount of prior nonreinforced exposure to the stimuli surrounding a stressful event. The histories of most adults include many painful experiences within a medical setting. Stimuli that precede these painful experiences may become conditioned stimuli capable of eliciting anxiety. One of the most reliable formulations coming out of the experimental laboratory is Pavlov's original finding that presentation of the conditioned stimulus in the absence of the unconditioned stimulus leads to extinction of the learned response. Extinction of conditioned fear has been shown to be a positive function of the number and duration of exposures to the conditioned stimulus (Shipley, 1974). Fear can also be generated by exposure to novel stimuli, and it is likely that novel medical procedures elicit this unconditioned fear. As with conditioned fear, the rate of habituation to novel stimuli has generally been found to be a function of the number and duration of stimulus exposures (Graham, 1973).

Extrapolating from this research to the preparation-for-stress area, it was hypothesized that the more exposures a person receives to a preparation message, the less fear will be experienced during the actual stressful event. The amount of stimulus preexposure is not viewed as an alternative to the provision of accurate information or to modeling of coping responses. Instead, it represents another factor that may contribute to the observed beneficial effects of preparation routines and that may be used to design more effective preparation messages.

In the present study, amount of stimulus preexposure to a real-life threatening medical examination was manipulated. Patients scheduled to receive an upper-gastrointestinal endoscopy viewed a videotape of an actual endoscopy either zero, one, or three times; an unrelated control tape was viewed by the "zero" control group. An attempt was made to control the effects of accurate information by providing all subjects with extensive verbal information about the endoscopy. Imitation of coping responses was minimized by use of a model who appeared fearful throughout the endoscopy.

The endoscopy examination seems to be well suited to the study of real-life stress (Johnson

& Leventhal, 1974; Johnson, Morrissey, & Leventhal, 1973). It involves the insertion of a flexible fiberoptic endoscope, 12 mm in diameter, through the mouth and into the gastrointestinal tract. Air is pumped into the gut to make its interior more visible, and the endoscope is manipulated for approximately 15-30 minutes while the physician views the lining of the gastrointestinal tract. Patients judged to be particularly anxious are sedated prior to the examination, but they are not anesthetized, since their active cooperation contributes to the success and safety of the examination. Patients view endoscopy as stressful, and it is easier to study than stressful procedures such as surgery because endoscopy is more time limited. Since patients remain awake during the examination, they are able to demonstrate and assess their distress. The fact that the patient must lie relatively still allows reliable measurement of physiological arousal.

Prior research has suggested that the effect of a preparation message may depend on the individual's characteristic method of coping with stress (Andrew, 1970; DeLong, 1971). The present study included a questionnaire measure of repression-sensitization coping style. Repression-sensitization is a unidimensional categorization, with repressors at one end of the continuum and sensitizers at the other. Sensitizers are generally described as handling stress by being vigilant, overtly anxious, alert to threatening cues, and by using intellectualization as a defense. They actively seek information about a stressor as a means of preparing to experience it. Sensitizers were expected to be initially high in anxiety and to show a monotonic decrease in anxiety as a function of the number of exposures to the preparation videotape. Repressors, on the other hand, are generally described as being overtly nonanxious and as dealing with the threat of impending stress by not thinking about it, repressing it, or denying its potential stressfulness.

It was hypothesized that repressors would be initially low in anxiety but that one exposure to an explicit videotape of the endoscopy examination would reduce their repressing defenses, resulting in increased distress. Repressors were expected to respond to additional exposures to the preparation tape with a

decrease in anxiety similar to that predicted for sensitizers. Thus, repressors who viewed the preparation tape once were expected to demonstrate greater anxiety than those viewing an unrelated control tape. Repressors who viewed the tape three times were expected to show less anxiety than those who received only one exposure to the tape.

Method

Subjects

The subjects were 60 hospitalized patient volunteers who had received no prior endoscopy examinations and who had been scheduled to receive an upper-gastrointestinal endoscopy at the Harry S. Truman Memorial Veterans Hospital in Columbia, Missouri. The 60 subjects consisted of 50 males and 10 females, ranging in age from 22 to 80, with a mean age of 53.0. Twenty subjects were randomly assigned to each experimental condition. Patients were not invited to participate in the study if they could not read or if they were judged to be disoriented or physically unable to complete the experimental procedures.

Measures of Anxiety

Anxiety is considered to be a multidimensional construct that may be reflected in physiological response, observable behavior, and self-report (Lang, 1968). Measures were selected to assess each of these response classes.

Physiological measures. During the endoscopy, heart rate was monitored with a Hewlett Packard Model 7788A polygraph using three fluid column electrodes. Respiration rate and skin conductance were also monitored. Respiration was not analyzed. Skin conductance data are not reported due to questionable validity stemming from inconsistent electrical grounding of the different endoscopes used and to attenuation of electrodermal responding by the atropine administered to all subjects (Lader & Montagu, 1962).

Behavioral measures. A physician-nurse anxiety rating scale, completed after the endoscopy examination by both the patient's endoscopist and nurse, was designed to assess the patient's fear during three time periods: (a) prior to insertion of the endoscope (before scoping), (b) while the endoscope was in the gastrointestinal tract (during scoping), and (c) after removal of the endoscope (after scoping). The scale consists of eight items (e.g., "Patient appears anxious before the tube is passed—gritting teeth, tight muscles, sweating, etc.") to be rated on a 5-point scale ranging from "not at all" to "very much." The item ratings made by the physician and nurse were combined, since Pearson product-moment correlations between the independent ratings were moderate and significant, $r(58) = .44-.55$, $p < .001$. Three summary anxiety ratings were then obtained by averaging the items within the before,

during, and after scoping time periods. The internal consistency of these three subtests ranged from .80 to .87, using Cronbach's (1951) alpha.

A second behavioral indicator of anxiety was whether the patient received diazepam (Valium) intravenously prior to an attempt to pass the endoscope. Only those patients judged by the physician to be highly anxious were given diazepam.

Self-report measures. Two questionnaires were used to obtain self reports of anxiety: the Spielberger State-Trait Anxiety Inventory (STAI) and the Post-Endoscopy Interview Schedule. The STAI (Spielberger, Gorsuch, & Lushene, 1970) consists of two separate 20-item scales. The Trait Anxiety (A-Trait) scale assesses anxiety proneness, and the State Anxiety (A-State) scale measures momentary or situational anxiety. The A-State scale was expected to reflect changes in anxiety level over time and was administered prior to the experimental manipulations as well as before and after the endoscopy. Scores on the A-Trait scale were not expected to differ between groups or to change over time (Spielberger, Auerbach, Wadsworth, Dunn, & Taubee, 1973). It was administered after the endoscopy primarily for descriptive purposes and to allow for calculation of correlations between measures of trait anxiety, state anxiety, and repression-sensitization.

The Post-Endoscopy Interview Schedule was used in a structured inquiry into the patient's reaction to the examination. Consisting of both open-ended questions and items to be rated on a 5-point scale, it was used to obtain a retrospective self-assessment of anxiety during the preparation videotape, before the endoscopy examination, and during the examination. Information was also gathered on the degree of annoyance and physical discomfort experienced during the examination and prior hospitalizations.

Measure of Coping Disposition

A Modified Repression-Sensitization (R-S) Scale, developed by Epstein and Fenz (1967), was used to classify patients as to their characteristic way of dealing with anxiety-provoking stimuli. The Modified R-S scale was developed in an attempt to eliminate the high (around .90) correlation between Byrne's Minnesota Multiphasic Personality Inventory derived R-S scale and measures of anxiety (Byrne, 1964).

Procedure

Each patient in the study, regardless of treatment condition, routinely received information about the endoscopy on three separate occasions—from the physician, the nurse, and the experimenter. The patient was told of the need for the examination, the procedure that would be followed, likely subjective sensations, and that would be followed, likely subjective sensations, and that would be followed, likely subjective sensations. The evening possible but improbable complications. The evening before the endoscopy, the patient was asked to participate in the research study and to sign a consent form. The Spielberger A-State scale and the Modified R-S scale were then completed, and, depending on prior random assignment, the patient was shown the control videotape once, (Group E0), the experimental tape videotape once, (Group E1), or the experimental tape three times

Figure 1. Mean physician-nurse anxiety rating before, during, and after scoping for each of the treatment conditions. (E0, E1, and E3 refer to the groups that viewed the control tape once, the experimental tape once, or the experimental tape three times, respectively.)

(Group E3). Subjects were instructed to watch each tape in its entirety. (Monitoring of time spent looking directly at the tape confirmed that subjects actually received the amount of exposure intended.)

The 18-minute experimental videotape showed a 35-year-old white male patient actually receiving an endoscopy. The patient in the tape showed an "average" amount of distress during the examination, gagging several times and requiring a moderate amount of "calming talk" by the nurse. The 26-minute control videotape was titled *Because I was too Young: The Memoirs of a Distinguished Indiana Physician*.¹

On the morning of the endoscopy, each patient received an intramuscular injection of .6 mg of atropine to reduce oral and stomach secretions, and the A-State scale was completed for the second time. Between 5 and 30 minutes later, the patient was taken into the endoscopy area, and electrodes were attached for the physiological measurements. After the physiological recordings stabilized, a 2-minute baseline was recorded.

Two physicians and a nurse then joined the experimenter in the endoscopy area. All present were blind as to the patient's experimental condition. The patient's throat was sprayed with a local anesthetic (1% Pilocaine), and, if judged necessary by the physician, Valium was administered. For those subjects who received Valium, the dosage ranged from 1.0 mg to 15.0 mg, with a mean of 7.7 mg. The physiological data were recorded for at least 1 minute prior to first placing the endoscope inside the patient's mouth and for 10 minutes thereafter. The experimenter also recorded (a) number of attempts necessary to insert the endoscope past the superior esophageal sphincter, (b) time required to insert the endoscope past this sphincter, (c) amount of gagging, and (d) name of the physician passing the endoscope. None of these factors, however, differentiated between experimental conditions.

Immediately after completion of the examination, the physician and nurse independently completed the physician-nurse anxiety rating scale. From 2 to 4 hours

after the examination, the Post-Endoscopy Interview Schedule was used to question the patient, and the STAI was completed by the patient.

Results

The results, as a whole, support the prediction that fear during a stressful medical examination would be reduced as a function of the number of prior viewings of a preparation videotape.

Premanipulation Comparisons

Analysis of variance of pretreatment variables revealed that subjects in the three treatment conditions were comparable in age, male-female ratio, reported days of previous hospitalization, and scores on both the Modified R-S scale and the Spielberger A-State scale.

Analyses

Two separate analyses of the data were performed. In the primary set of analyses, the repression-sensitization dimension was ignored and three one-tailed planned comparisons (i.e., E0 vs. E1, E1 vs. E3, and E0 vs. E3) were made for each dependent variable. These were based on the prediction that E3 would evidence the least distress, E1 more distress, and E0 the most distress. Unless otherwise noted, comparisons were made with *t* tests using the appropriate error term from a one-way analysis of variance or, where three repeated measurements were obtained, from a 3×3 analysis (Treatment Condition \times Time Period). The degrees of freedom for the pooled error term, used where repeated measures were obtained, was determined by Satterthwaite's formula (Winer, 1971). A second set of analyses was performed to determine the relationship between coping style and the dependent variables.

Behavioral Measures

Physician-nurse anxiety rating scale. Figure 1 shows the mean anxiety rating by time

¹ *Because I was too Young: The Memoirs of a Distinguished Indiana Physician* can be obtained from the Instructional Media Resource Center, Indiana University School of Medicine, Indianapolis, Indiana 46202.

periods for each of the treatment conditions. The standard deviations for these data ranged from .80 before scoping to .52 after scoping. The E3 subjects were rated significantly less anxious than the E0 subjects both before and during scoping, $t(84) \geq 2.19$, $p < .025$. Group E1 was rated significantly less anxious than E0 during scoping, $t(84) = 1.95$, $p < .05$. The other comparisons did not reach significance.

Tranquilizer required. Diazepam was required by a significantly lower proportion of the E3 patients (20%) than either the E0 patients (45%) or the E1 patients (50%); $z \geq 1.69$, $p < .05$.

Heart Rate

Heart rate during the final minute of the baseline period did not differ between groups, $F(2, 56) < 1.00$.² Heart rate change scores were computed for three time periods by subtracting this basal heart rate from (a) heart rate during the minute immediately prior to insertion of the endoscope, (b) mean heart rate during the first 5 minutes following insertion of the endoscope, and (c) mean heart rate during the second 5 minutes following insertion of the endoscope. The groups did not differ significantly during the minute just prior to insertion of the endoscope. During the first 5 minutes of scoping, Group E3 had significantly less heart rate increase ($M = 18.53$, $SD = 9.39$) than both Group E1 ($M = 27.92$, $SD = 15.84$), $t(101) = 2.64$, $p < .01$, and Group E0 ($M = 24.78$, $SD = 13.58$), $t(101) = 1.80$, $p < .05$. During the second 5 minutes of scoping, the groups did not differ significantly (M s = 16.66, 19.00, and 14.04 for Groups E0, E1, and E3, respectively).

Self-report Measures

STAI. The groups did not differ significantly from each other in state anxiety just prior to the endoscopy. Group means for E0, E1, and E3 were 43.30, 37.80, and 42.25, respectively. Following the endoscopy, the groups were ordered in the predicted direction on state anxiety (M s for E0, E1, and E3 were 39.95, 33.75, and 29.20, respectively), with significance reached for the E0 versus E1 comparison, $t(109) = 1.74$, $p < .05$, and the E0 versus E3 comparison, $t(109) = 3.02$, $p < .005$. As expected the groups did not differ

significantly in trait anxiety after the endoscopy (two-tailed tests). Group means for E0, E1, and E3 were 43.3, 36.0, and 39.5, respectively.

Post-endoscopy interview schedule. The control tape was rated as comparable to the experimental tape in both interest value ($M = 3.7$ for E0, 3.9 for E1, and 4.0 for E3) and the generation of emotional upset ($M = 2.0$ for E0, 2.3 for E1, and 2.0 for E3). Consistent with the habituation/extinction hypothesis, Group E3 rated the third viewing of the experimental tape as less upsetting ($M = 1.5$) than the first viewing of the tape ($M = 2.0$), $t(19)$ for correlated means = 2.78, $p < .005$. The groups were comparable in subject response to the question, "Do you feel that you got too little or too much information about the coming endoscopy?" (M s = 3.1-3.2). No subject indicated that too little information was received.

There were reliable group differences in amount of reported annoyance. To the open-ended question, "Very often some parts of an endoscopy examination cause annoyance. What things annoyed you?" one or more complaints were voiced by nine E0 subjects, eight E1 subjects, and only two E3 subjects. Proportion tests indicated that the number of E3 subjects voicing complaints was significantly lower than the number in either E0 or E1 ($z \geq 2.19$, $p < .025$). Asked to rate how annoyed they felt during the endoscopy, E0 subjects indicated higher annoyance ($M = 1.9$) than either E1 or E3 subjects ($M = 1.4$ for both groups), $t(57) \geq 1.70$, $p < .05$. The groups did not differ in ratings of anxiety experienced during the hour before the endoscopy or in ratings of anxiety and physical discomfort experienced during the endoscopy.

Repression-Sensitization

The dependent variables were also analyzed for differences as a function of subjects'

²One subject was dropped from the heart rate analyses because of failure to obtain a valid basal heart rate. He had the highest basal rate of any patient (111 bpm) and was the only subject to exhibit a drop in heart rate during the stressful endoscopy, demonstrating that a true basal heart rate measurement had not been obtained.

Figure 2. Mean heart rate increase during the first 5 minutes of scoping for repressors and sensitizers in each of the treatment conditions. (E0, E1, and E3 refer to the groups that viewed the control tape once, the experimental tape once, or the experimental tape three times, respectively.)

repression-sensitization score. The 10 subjects whose R-S score fell at the median (12) were eliminated from these analyses, leaving 25 repressors (with scores between 5 and 11) and 25 sensitizers (scores = 13-21). Planned comparisons were used to test the predictions that sensitizers would show a monotonic decrease in anxiety as a function of the number of times they viewed the preparation tape ($E0 > E1 > E3$) and that repressors would show an inverted-U-shaped function, with E1 evidencing the greatest anxiety ($E0 < E1 > E3$). Each comparison was made with a one-tailed *t*-test using the appropriate error term.

Physician-nurse anxiety rating scale. Sensitizers in Group E1 were rated as significantly less anxious than those in Group E0 before, during, and after scoping, $ts(67) \geq 1.75$, $p < .05$. No other comparisons for sensitizers or repressors reached significance.

Tranquilizer required. The percentage of patients in each group requiring diazepam followed the predicted pattern for repressors (% tranquilized = 42, 67, and 9 for E0, E1, and E3, respectively), with the E1 versus E3 comparison reaching significance ($z = 2.58$, $p < .005$). For sensitizers none of the comparisons were significant (% tranquilized = 56, 67, and 43 for E0, E1, and E3, respectively).

Heart rate. There were no significant differ-

ences in heart rate change scores during the minute immediately prior to insertion of the endoscope. Figure 2 provides mean heart rate increases during the first 5 minutes of scoping for repressors and sensitizers in each experimental condition. Sensitizers showed the predicted monotonic decline in heart rate increase, with the E0 versus E3 comparison reaching significance, $t(76) = 2.43$, $p < .01$. Support was also received for the prediction that E1 repressors would have higher heart rate increases than repressors in either E0 or E3, $ts(76) \geq 2.46$, $p < .01$.

A similar pattern was observed during the second 5 minutes of scoping. Sensitizers in E3 showed less heart rate increase ($M = 8.43$) than sensitizers in E0 ($M = 21.04$), $t(76) = 2.27$, $p < .025$. Heart rate increase for sensitizers in E1 ($M = 16.52$) fell between E0 and E3 but did not differ significantly from either of these groups. For repressors, no differences reached significance, but the pattern of results was similar to that observed in the first 5 minutes of scoping. Means for E0, E1, and E3 repressors were 13.31, 21.65, and 16.27, respectively.

State anxiety. There were no differences between groups in state anxiety reported before the endoscopy. After the endoscopy, E1 and E3 sensitizers reported significantly less anxiety than E0 sensitizers, $ts(79) \geq 2.17$, $p < .025$ ($Ms = 44.78$, 33.22, and 29.00 for Groups E0, E1, and E3, respectively). The comparisons on repressors for this time period were not significant.

Post-endoscopy interview schedule. None of the comparisons reached significance for any of the postendoscopy interview items.

Intercorrelations Between Selected Dependent Variables

Table 1 provides Pearson product-moment intercorrelations between the various measures of anxiety and scores on the Modified R-S scale. Intercorrelations between physiological, behavioral, and self-report measures of anxiety were low but frequently significant. Intercorrelations between different self-report measures were moderate. The low nonsignificant correlation between amount of Valium and mean heart rate shows that Valium did not confound the heart rate data.

Discussion

The results support the hypothesis that fear during a stressful procedure is reduced as a function of the number of prior viewings of a preparation videotape. The ordering of the treatment conditions on the dependent measures was impressively consistent, with E3 generally evidencing the least anxiety, E1 more anxiety, and E0 the most anxiety.

The results are consistent with an extinction/habituation hypothesis. According to this formulation, three exposures to endoscopy-related stimuli resulted in greater habituation and/or extinction of emotion than did one exposure. Likewise, one exposure to the tape produced greater habituation and/or extinction than no exposure. This interpretation is supported by the fact that subjects in the E3 condition rated their third viewing of the tape as less upsetting than their first viewing.

At first glance these results appear similar to those of studies on the vicarious extinction of phobic snake avoidance. Bandura, Blanchard, and Ritter (1969) and Blanchard (1970) found that rated fear and behavioral avoidance decreased as a function of the amount of exposure to filmed models handling a snake. However, in these studies the feared and avoided situation was actually harmless, and the models were pictured as appropriately calm and happy. By contrast, in the present study, the feared situation (endoscopy) was actually aversive and unavoidable. The filmed model

was shown as experiencing discomfort (e.g., gagging, tight muscles, distressed look on face). Since calm behavior was not modeled, it is unlikely that subjects learned to be calmer during the endoscopy through matching their response to that of the model.

The model used in the present study might be labeled a *flooding model* or a *realistically anxious model*, since he showed distress throughout the endoscopy. Several investigators (Kazdin, 1974; Meichenbaum, 1971) have found the viewing of coping models (i.e., those showing initial distress followed by calm contact with the feared object) to be more effective in reducing fear and avoidance than viewing mastery models (i.e., those appearing calm throughout). Theoretically, the sequence of viewing a fearful model become calm facilitates subject identification and imitation. However, the positive findings of the present study using a flooding model suggest that the superiority of results with a coping model may result from the viewing of a fearful model per se rather than from the sequence of viewing a fearful model followed by viewing a calm model. Subject identification with a fearful model can lead to vicarious arousal. When this arousal is maintained long enough and is not reinforced by painful stimulation, it extinguishes. If this were the case, a flooding model would result in greater arousal reduction than a coping model, since the flooding model is fearful throughout the taped sequence rather than only initially. This hypothesis could be

tested by comparing the effectiveness of various amounts of exposure to mastery, coping, and flooding models in producing reductions in arousal.

Another possible explanation for the present findings is provided by the accurate expectancy theory. According to this formulation, the E3 subjects who repeatedly viewed the preparation tape learned more about the endoscopy examination and formed a more accurate expectancy of what was in store for them. This is possible but unlikely, since all groups received detailed verbal information about the examination on at least three separate occasions. The endoscopy examination is relatively simple to understand, and it seems likely that near maximal information was acquired by subjects in all three treatment conditions. In fact, following the endoscopy, the groups were comparable in rated amount of information received, and all subjects indicated they had received enough information. Nevertheless, the experimental design could have been strengthened by administering a test of knowledge about endoscopy just prior to the examination. Andrew (1970) used such a procedure and found no correlation between information learned from an audio preparation-for-surgery tape and her dependent variables.

Another possible explanation for the present results is that the operative variable was simply time spent viewing a videotape, regardless of the content of the tape. However, despite the fact that the control tape was 8 minutes longer than the experimental tape, the E1 subjects evidenced less anxiety than E0 subjects on most of the dependent measures. The results cannot, therefore, be attributed solely to length of viewing time.

Regardless of the theoretical explanation of the results, the finding that anxiety during a stressful medical examination was reduced as a function of the number of prior viewings of a videotape of the examination is of potential practical importance. It suggests that explicit repetitive preparation for stress may be beneficial.

An area of both practical and theoretical concern is the interaction of subject characteristics with the preparation message. In the present study, sensitizers showed the predicted monotonic decrease in anxiety as a function of

the number of videotape viewings. Repressors showed the predicted inverted-U-shaped function for the heart rate and diazepam data, with E1 subjects evidencing the greatest arousal. These findings are consistent with the hypothesis that repressors maintain low arousal in the face of threat by not thinking about it and not seeking information. Theoretically, one exposure to the explicit stimuli of the preparation tape weakened their repressing defenses and left them in an aroused state similar to that of unprepared sensitizers. In E3 the two additional viewings of the tape diminished or extinguished this arousal.

The finding that one viewing of the preparation tape produced increased anxiety in repressors is consistent with the findings of Andrew (1970) and Delong (1971). Delong (1971) found that sensitizers who heard one brief preparation message prior to surgery had less complications and were discharged sooner than sensitizers hearing a control tape. Repressors who heard the preparation tape did not show this positive outcome, and, in fact, they expressed more complaints postoperatively than repressors hearing the control tape. Andrew (1970) also found negative effects for repressors who heard a short audiotape. They required more pain and sleeping medications after surgery.

These results suggest that repressors and sensitizers might benefit from different preparation strategies, with sensitizers prepared extensively and repressors left alone or at least left with their defenses. Repressors might be exposed to a preparation message that supports their defenses by minimizing danger or encouraging avoidance through selective attention. Though they did not differentiate their patient subjects on the repression-sensitization dimension, Langer, Janis, and Wolfer (1975) found beneficial effects from a 20-minute verbal preparation-for-surgery message emphasizing cognitive defensive strategies such as calming self-talk and selective attention. Perhaps this type of preparation message would prove especially effective with repressors.

Taken as a whole, the present study demonstrates that reasonably well-controlled research on preparation for stress can be conducted in real-life stressful situations. This is of particular interest at a time when increased concern for

subjects' welfare and the need for comprehensive informed-consent procedures make the use of analogue populations and stressors less tenable. In addition, findings obtained in a real-life stressful situation seem more likely to generalize to other real-life situations than results obtained in analogue studies that must use relatively low-intensity stressors. Nevertheless, the present findings need to be extended to other settings. This is particularly true of the regression-sensitization findings. As Averill, Olbrich, and Lazarus (1972) noted, findings of relationships between personality variables and stress reactions have tended to "disappear when tested in a slightly different setting" (p. 29).

Addict Descriptions of Therapeutic Community, Multimodality, and Methadone Maintenance Treatment Clients and Staff

Patricia B. Sutker, Albert N. Allain, and Charles J. Smith
Department of Psychiatry and Behavioral Sciences
Medical University of South Carolina

Gary H. Cohen
Tulane University School of Medicine

Adjective Check List (ACL) descriptions of 88 addicts in treatment toward methadone maintenance, multimodality, and therapeutic community clients and program staff within and across rating groups representing the three types of drug treatment conditions were compared. Data analysis procedures included single-groups analyses of variance; combined-groups analyses of covariance with sex, age, race, months addicted, months in treatment, and scores on the Raven Progressive Matrices treated as covariates; and principal-components analysis. Addicts as a group were characterized by high elevations on ACL scales Aggression and Succorance. Client descriptions varied significantly as a function of category rated, with program staff described more positively than client groups, therapeutic community residents described more favorably than other client groups, and methadone clients rated with marked negativity. Between-category differences were most succinctly summarized by factor score comparisons on General Adjustment, one of four factors identified by principal-components analysis and differentially associated with all four categories rated. Results suggest that addict opinions represent a valuable source of ideas for evaluating current treatment approaches and identifying self- and staff perceptions of therapeutic significance.

Treatment successes have been limited among therapeutic approaches to opiate addiction, and pessimism has characterized reports of treatment outcome studies evaluating the effectiveness of strategies such as methadone

This research was supported by General Research Support Grant 22620-GR26 from the Medical University of South Carolina to the first author and was presented at the annual meeting of the Southeastern Psychological Association in New Orleans, Louisiana, March 1976. Special appreciation is expressed to Maggie Pike and Barry Pike of Odyssey House Louisiana and to Ward Suddereth of the Drug Research Clinic who made access to clients in these treatment modalities possible. Appreciation is also expressed to Joanne B. Yoder, Gary S. Gilbert, and John Mehlhorn who assisted in data collection and to Phyllis Goldberg and Larry Libater for instrument scoring.

maintenance, multimodality programming, and the therapeutic community. Predicting the long-range fate of addict clients treated in traditional fashion at the U.S. Public Health Service Hospital at Lexington, Vaillant (1970), estimated that 29% of addicts at risk become permanently abstinent each year. Similarly, methadone maintenance programs have been regarded as only partially successful in meeting earlier claims (Dole & Nyswander, 1976), and although Williams and Lee (1975) showed positive behavioral and attitudinal changes among addicts remaining in methadone treatment longer than 3 months, they described a high dropout rate. Other investigators reported that methadone clients continue to use illicit drugs (Chambers & Taylor, 1972) and view methadone as an undesirable solution to their problems (Sutker, Allain, & Moan, 1974). Evaluations of therapeutic communities, however, have been somewhat more positive, and

of those treatment conditions studied over extended time frames the therapeutic community seems to have achieved greatest success (Collier & Hijazi, 1974; Sugarman, 1974). Additionally, short-term personality changes have been associated with residence in therapeutic communities, hospitals, and even prisons (Sutker, Allain, & Cohen, 1974; Zuckerman, Sola, Masterson, & Angelone, 1975).

Although several studies have explored changes in personality, attitudes, or behavior associated with therapeutic intervention, there have been no reports of attempts to collect data in comparable fashion across treatment conditions. Among other difficulties, variability in situational and temporal factors and sampling populations from diverse treatment groups have posed formidable problems for design and have restricted investigators in conducting meaningful comparative research. Additionally, studies attempting to evaluate treatment effectiveness have focused on personality or performance variables, and assessment of the personal attitudes of addict clients themselves toward available treatment approaches, clients, or staff has rarely been an experimental goal. Attitudinal studies have been limited to perceptions of single-treatment modalities (Brown, Bass, Gauvey, & Kozel, 1972; Crowther & Pantleo, 1971), and the consumers of drug treatment services, or addict clients, have been largely overlooked as a source of ideas for systematic evaluation of treatment options.

Assuming that potential or participating clients are information-processing beings whose perceptions of situations provide one key to understanding how they will respond within specific milieus, attitudinal sets may influence client selection and degree of participation within given programs as well as provide valuable information regarding client-perceived successfulness of treatment possibilities. Therefore, the purpose of this investigation was (a) to describe attitudes of addict clients in therapeutic community, multimodality, and methadone maintenance programs toward clients in these conditions and their own program staff and (b) to make comparisons of addict attitudes toward treatment conditions within and across client category groups. It was reasoned that attitudes toward treatment conditions

would best be reflected in measures that required client-rating descriptions of the most obvious products of a treatment program—program clients and staff.

Method

Subject Selection

To sample attitudes toward drug treatment strategies across treatment categories, three programs in New Orleans representing the therapeutic community, methadone maintenance, and multimodality approaches were contacted to request access to program clients. Subsequent to explanation of study purposes and procedures, agreement to participate was obtained from (a) Odyssey House Louisiana, a highly structured therapeutic community with approximately 50 residents, which requires long-term commitment and drug abstinence (client-staff ratio of 6:1); (b) the Drug Research Clinic, a methadone maintenance program with an approximate census of 160, which makes relatively limited demands for individual or group therapeutic involvement (client-staff ratio of 16:1); and (c) the Narcotic Addict Rehabilitation Act Program (NARA), administered by the Department of Psychiatry and Neurology of Tulane University School of Medicine, which offers inpatient treatment and outpatient counseling including methadone maintenance, chemotherapy, and drug-free regimes to approximately 60 clients (client-staff ratio of 6:1).

Each program allowed initial access to clients through individual or group discussions for explanation of the research project. Roughly half of NARA and Drug Research clients were approached following regular appointments, and Odyssey clients were seen in a large group assembled by program staff. Selection was voluntary but with personal solicitation, program encouragement, and promise of \$5 payment. Participation rates in terms of initial willingness varied across programs and ranged from 99% of Odyssey, 95% of NARA, and 70% of Drug Research clients contacted. Of 163 volunteers expressing interest, 75 were eliminated: 11 were unable to read sufficiently well; 61 were unable or unwilling to complete procedures, and 3 had not been enrolled at least 3 months in their specific treatment condition. Dropouts were evenly distributed for NARA and Drug Research programs but were nonexistent among Odyssey residents.

The final sample of 88 treatment addicts included 28 multimodality or NARA clients, 36 therapeutic community or Odyssey residents, and 24 methadone maintenance or Drug Research clients. Racial and sexual composition of treatment programs is presented in Table 1, which reflects an uneven distribution of women, $\chi^2(2) = 6.96$, $p < .05$, and blacks, $\chi^2(2) = 26.92$, $p < .01$, across samples. Distributions were, however, generally representative of breakdowns within sample populations. A summary of subject personal characteristics is outlined in Table 2, and it can be seen that groups differed significantly in age, Raven scores, months addicted to opiates, and months in treatment,

Table 1

Percentage Breakdown by Race and Sex Among Multimodality, Therapeutic Community, and Methadone Maintenance Clients

Treatment group	White	Black	Male	Female
Multimodality—NARA	64	36	93	7
Therapeutic community—Odyssey	83	17	75	25
Methadone maintenance—Drug Research	17	83	62	38

Note. $n = 88$. NARA = Narcotic Addict Rehabilitation Act Program.

which necessitated careful statistical handling of between-group comparisons. All groups shared a long history of opiate addiction, and even the more youthful Odyssey residents were characterized by a mean length of addiction greater than 3 years. Subjects across treatment groups showed a mean of 28 months in drug treatment programs.

Materials and Procedure

Subjects were administered a battery of instruments, which included the Raven Progressive Matrices and four versions of the Adjective Check List (ACL; Gough & Heilbrun, 1965). Used among socially deviant groups in the past (Sutker & Moan, 1973), the Raven was selected to reflect general intellectual or problem-solving ability without undue bias of academic sophistication. The ACL, a self-administered inventory of 300 adjectives yielding scores on 24 need scales, was chosen because it has also been used successfully among addict samples (Brown et al., 1972) and provides a profile of personality attributes. The ACL format was presented four times to subjects who were asked to indicate those adjectives that best described addict clients in a multimodality program, in a methadone maintenance program, in a therapeutic community, and their own program staff. It was reasoned that ratings of clients in the various treatment programs would reflect attitudinal sets and opinions toward the treatment conditions themselves.

Data Analysis

Although treatment groups shared a history of chronic opiate use, criminal activity, and familiarity with drug treatment (over 68%, evenly distributed across sample groups, reported experience with at least two treatment conditions), they differed on several personal characteristic variables as seen in Table 2. In part, differences reflect the complexities of attempting to execute comparative research over varied clinical settings, but sampling to avoid such differences may have rendered samples poorly representative of the groups from which they were drawn. Recognizing the limitations of study implementation, three approaches were pursued in data analysis. Preliminary procedures compared attitudes toward treatment client categories within rating groups by one-way analyses of variance with repeated measures for each ACL scale, and Tukey's tests were performed to evaluate differences for all possible comparisons in which F ratios for categories rated were significant. It was reasoned that extraneous or unplanned between-group differences would in no way contaminate interpretation of these results. Second, attitudes toward treatment client categories were compared within and between rating groups for each ACL scale using Groups \times Categories repeated measures analyses of covariance with sex, race, age, months addicted, months in treatment, and Raven scores included as covariates. The number of independent variables was within suggested limits for sample

performed to identify independent constellations of variables accounting for the major portion of total variance and to provide a concise basis for differentiation of groups in relation to ACL variables.

Results

Within-groups comparisons of client responses across staff and client categories showed that descriptions varied depending on the category rated, and a total of 46 differences were significant at the .05 level of probability. Similar distributions of ACL profile configurations were produced within rating groups, with staff regarded most positively and methadone clients most unfavorably. These relationships are illustrated in Figure 1, which presents mean ACL profile patterns for each category rated within the three treatment groups sampled. Results of within-groups analyses are not reported in greater detail, because mean ACL values differed at most by only tenths of a point from adjusted means derived from combined groups analyses (see Table 3).

Inclusion of sex, race, age, months addicted, months in treatment, and Raven scores as covariates diminished the range of scores by adjusting methadone client ratings in the more positive direction and multimodality and

therapeutic community ratings more negatively. There were, however, differences between and within groups that exceeded the .05 confidence level for statistical significance. Combined groups of treatment clients distinguished among ratings categories in assigning descriptors with significant differences on 22 of 24 ACL scales as seen in Table 3, and inspection of Figure 2 reveals distinct group separation in distribution of ACL configurations. Program staff were described more positively than other groups, followed in order by therapeutic community, multimodality, and methadone clients. Adjectives used to describe methadone clients were most critical and differed from those attributed to therapeutic community residents, multimodality clients, and program staff on 22, 18, and 20 scales, respectively. Ratings of multimodality clients were less favorable than those reported for therapeutic community residents on 17 scales and program staff on 19 scales, and ratings of program staff and therapeutic community residents differed on 13 scales, with staff regarded more favorably.

Treatment groups produced different descriptions of client categories, and Groups \times Categories interaction terms were significant

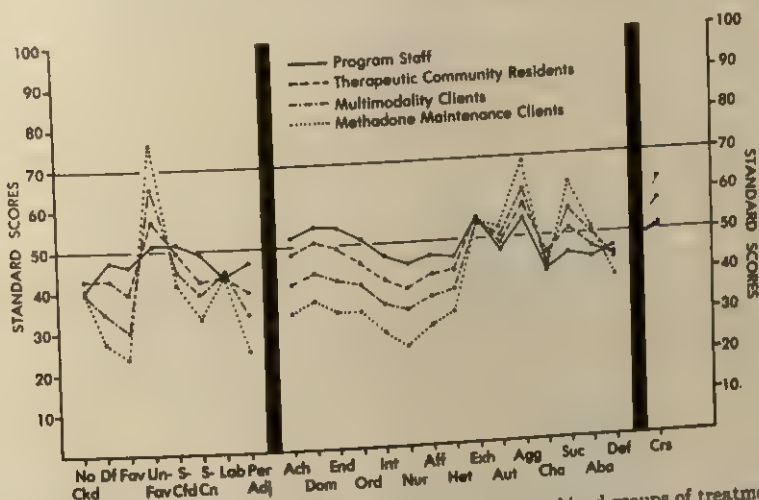

Figure 2. Mean Adjective Check List profile patterns produced by combined groups of treatment clients for four categories rated. (No. Ckd = Number of Adjectives Checked; Df = Defensiveness; Fav = Number of Favorable Adjectives Checked; Unfav = Number of Unfavorable Adjectives Checked; S-Cld = Self-confidence; S-Cn = Self-control; Lab = Lability; Per Adj = Personal Adjustment; Ach = Achievement; Dom = Dominance; End = Endurance; Ord = Order; Int = Intracception; Nur = Nurturance; Aff = Affiliation; Het = Heterosexuality; Exh = Exhibition; Aut = Autonomy; Agg = Aggression; Cha = Change; Suc = Succorance; Aba = Abasement; Def = Deference; Crs = Counseling Readiness.)

for 21 scales (see Table 3). Multimodality clients described themselves and therapeutic community residents similarly but pictured methadone clients more negatively than themselves and therapeutic community residents on 16 scales, including Number of Favorable Adjectives Checked, Number of Unfavorable Adjectives Checked, Self-control, Personal Adjustment, Achievement, Nurturance, and Succorance (see Figure 1). In contrast, they described staff more favorably than themselves on Number of Favorable Adjectives Checked, Self-control, Endurance, Intraception, Affiliation, and Aggression. Methadone clients produced a relatively homogeneous, negative assortment of responses with two significant differences. They described themselves as more succorant and less self-controlled than program staff. Inspection of Figure 1 shows an uncomplimentary choice of descriptors for all categories, with highest elevations on Number of Unfavorable Adjectives Checked, Aggression, Succorance, and Exhibition and lowest scores on Nurturance and Intraception. Therapeutic community descriptions were highly variable, with significant differences on 20 scales, and residents were positive in assessment of their own staff and clients but negative toward methadone and multimodality clients. Program staff, characterized by highest elevations on Self-confidence, Dominance, Achievement, and Endurance and lowest scores on Abasement, Succorance, Change, and Deference, was rated more positively than multimodality and methadone clients on 18 scales each. Therapeutic community residents described themselves less positively than staff on Number of Favorable Adjectives Checked, Self-confidence, Self-control, Personal Adjustment, Achievement, Dominance, Endurance, Order, Intraception, Change, and Succorance scales, but for the most part self-descriptions were in the positive range and followed the pattern attributed to staff with the exception of succorance ratings. Residents rated themselves more positively than multimodality and methadone clients, with significant differences on 20 scales, and they described methadone clients more negatively than multimodality clients on Achievement, Defensiveness, Dominance, Endurance, and Succorance. The latter treatment groups were characterized by prom-

inent elevations on Number of Unfavorable Adjectives Checked, Aggression, and Succorance, with low scores on Number of Favorable Adjectives Checked, Nurturance, Personal Adjustment, Intraception, Affiliation, and Achievement.

Between-groups comparisons of category descriptions showed that multimodality clients were viewed similarly by themselves and methadone clients, but therapeutic community residents attributed more negative adjectives to multimodality clients than did multimodality and methadone groups on 16 scales. Methadone clients were described by therapeutic community and multimodality clients more negatively than they rated themselves on 19 and 13 scales, whereas descriptions of therapeutic community residents tended to be consistent and positive. There were no differences among rating groups in descriptions of therapeutic community residents, with the exception that multimodality clients described residents as higher on Abasement than they viewed themselves. Finally, program staff ratings differed significantly depending on the treatment group. Therapeutic community residents described staff more favorably on Self-confidence, Achievement, Dominance, and Abasement scales than multimodality clients and more favorably than methadone clients described their staff on 8 scales including Self-confidence, Achievement, Dominance, Endurance, and Succorance. Multimodality clients assigned more favorable ratings to staff than did methadone clients on Number of Unfavorable Adjectives Checked, Endurance, and Nurturance.

Principal-components analysis generated four factors with eigenvalues greater than 1.0 as summarized in Table 4. Factor 1, accounting for 51% of the total variance and labeled *General Adjustment*, was characterized by significant loadings (.50 or greater) on 17 of 24 ACL scales including positive loadings for Endurance, Personal Adjustment, Intraception, Nurturance, Defensiveness, Self-control, Affiliation, Number of Favorable Adjectives Checked, and Achievement, and negative loadings for Aggression, Number of Unfavorable Adjectives Checked, and Succorance. Remaining factors accounted for small portions of the variance but are described as follows: Factor 2,

defined by high positive loadings for Autonomy, Exhibition, Aggression, Self-confidence, and Change, appeared to represent Assertiveness; Factor 3, with highest loadings for Abasement, Succorance, and Counseling Readiness, was labeled *Dependence*; and, Factor 4, labeled *Change*, was described by highest loadings for Number of Adjectives Checked, Liability, and Change.

To determine if independent clusters of personality needs represented by the four factors were differentially associated with

client rating groups or categories rated, standardized factor scores generated by principal-components analysis were subjected to univariate analyses of variance and Tukey's tests.¹ Although there were significant differences between and within groups, only differences associated with the categories effect are described in detail, $F(3, 255) = 178.95, 35.23$, and 6.29 for Factors 1, 3, and 4 ($ps < .01$). Constellations of personality needs defined by Factors 1, 3, and 4 were differentially related ($ps < .01$) to the four categories rated. Staff were characterized as higher than client groups on General Adjustment, with therapeutic community residents higher than multimodality and methadone clients and multimodality clients higher than methadone clients. Therapeutic community residents and staff were not described differently on Dependence, but ratings of both groups were significantly less associated with this factor than those for multimodality or methadone clients. Categories rated were also differentially associated with Change, with therapeutic community residents characterized as higher on this dimension than staff and methadone clients.

Discussion

Although treatment addicts shared similar response sets in rating client and staff categories, descriptions varied significantly over categories even with the effects of such potentially powerful variables as age, sex, race, months addicted, months in treatment, and Raven scores partialled out. Differences among category descriptions were most succinctly summarized by comparisons of factor scores on General Adjustment, which was differentially associated with all four categories rated. Staff were described more positively than client groups and were seen as more dominant, better adjusted, less changeable, and less succorant. If staff elicited the most positive descriptors, methadone clients provided the rating stimulus most negatively assessed. Client groups seemed to share a negative set of attitudes toward methadone clients, and by logical extension,

¹ Mean factor scores and F ratios for categories rated within treatment client groups are available on request.

methadone programs, and to evidence greater enthusiasm for multimodality and therapeutic community approaches.

Results are consistent with earlier reports of client pessimism regarding methadone maintenance (Brown et al., 1972; Dole & Nyswander, 1976; Sutker, Allain, & Moan, 1974). Methadone clients were described as more aggressive, more dissatisfied, more hostile and critical, less well-adjusted, less self-confident, and less likely to be dominant, independent, or achievement-oriented than other client groups. Although variations in client composition of treatment programs may have influenced such results, descriptions were relatively uniform across treatment conditions, suggesting that methadone clients were rated without regard for specific programs or client personal characteristics. Addict attitudes toward methadone clients and programs, as well as data from other studies summarized by Cohen, Howard, Klein, and Newfield (1976), do not allow resolution of contradictory viewpoints toward this type of treatment. However, among possible explanations for the nearly unanimous client negativity are perceptions of dubious long-range goals, slow progress toward behavioral change, and less client/staff contact. Whereas other treatment strategies use structure, supervision, and discipline to facilitate development of productive activity, personal independence, and achievement orientation, methadone programs can be seen primarily as mechanisms to sustain dependence on a drug identified with sedative effects and to minimize encounters with law enforcement. The combination of drug dependence and certain daily doses is also one that negates much of the purpose, activity, and excitement previously associated with drug use and client life-style (Preble & Casey, 1969). These speculations suggest the need to determine if methadone programs facilitate development of negative attitudes toward self and others even more than nontreatment, drug-taking conditions.

Clients across treatment categories seemed to hold therapeutic community residents, and perhaps programs, in relatively high esteem. Therapeutic community residents were particularly enthusiastic about themselves and their staff, although they viewed multimodality clients somewhat negatively and methadone

clients with marked disdain. Their variability in descriptor assignments, or response polarization, may be an outgrowth of the totality of program commitment required for continued participation as suggested by the cognitive dissonance model (Festinger, 1957) or evidence that clients strongly endorse program goals and methods. Interestingly, therapeutic community self-descriptions were congruent with the pattern of adjectives assigned to staff, suggesting a high degree of resident/staff identification. Perhaps because of constant interpersonal contact, or association of reinforcement with staff authority, therapeutic community residents aspire more than other groups to mimic their treatment models. The reasons that prompt treatment clients in other conditions to rate therapeutic community residents relatively positively are as yet unknown; however, in view of the extent of personal control relinquished in residential treatment, it is interesting that multimodality clients perceived therapeutic community residents as more inclined toward abasement than they saw themselves.

Despite group differences, clients described themselves in relatively unfavorable terms. Rating patterns across groups showed prominent elevations on Number of Unfavorable Adjectives Checked, Aggression, and Succorance. The results are consistent with reports by Reith, Crockett, and Craig (1975), which point to a constellation of features among addict self-descriptions including exaggerated dependency needs, difficulties in appropriate expression of hostility, excessive demands for interpersonal support and attention, and limitations in responding in kind. Mutual exaggeration of such features provides an important target for therapeutic intervention and assessment of program impact. Although present data do not support the contention that aggressiveness and excessive demands for attention precede initial opiate use, their early identification may signal individuals at high risk. Research exploring personality precursors of drug use and dependence must also take into account interactions with situational as well as more stable environmental, social, and motivational variables.

In summary, addict attitudes represent an interesting and largely untapped source of ideas that may be assessed systematically to

evaluate available treatment approaches and to identify self- and staff perceptions of therapeutic significance. The extent to which positive opinions of staff or fellow clients is related to program participation and ultimate treatment outcome should be explored concomitantly with performance and personality variables across program types in outcome evaluation. Research might also include attitudinal measurement as one methodology to specify treatment parameters perceived as operating within the therapeutic community framework, or conversely, associated with methadone maintenance programs that elicit positive or negative assessments across treatment and nontreatment addict groups and to predict individual performances within a given treatment setting.

Treatment of General Tension: Subjective and Physiological Effects of Progressive Relaxation

T. D. Borkovec, J. B. Grayson, and K. M. Cooper
University of Iowa

Experiment 1 found virtually no effects of type of no-treatment condition or demand/suggestion on the self-monitoring of daily tension percentage and severity among 43 overly tense college students during a 4-week baseline period. Subjects given four subsequent sessions of progressive relaxation did report significant reductions in tension, which were maintained at a 7-month follow-up. Experiment 2 included 36 overly tense college students and compared a no-treatment condition to groups given nine sessions of relaxation with versus without muscle tension release. Counterdemand instructions were in effect for the first seven sessions. Relaxation with tension release produced reductions in daily tension percentage significantly superior to no-treatment during the counterdemand period, whereas relaxation without tension release did not differ from either group. Treatment effects maintained at a 5-month follow-up. No treatment effects were found on several during-session physiological measures, although Session 1 physiological reduction predicted improvement in tension percentage. Presence or absence of tension release did significantly influence the number of relaxation cycles necessary to produce reports of deep relaxation, frequency of practice, and successfulness of eliminating daily tension at follow-up.

Tension and anxiety represent pervasive adjustment problems. Although these complaints commonly present themselves in outpatient and inpatient centers, the widespread occurrence of tension-related difficulties is aptly exemplified by the 77 million prescriptions for benzodiazepine antianxiety agents (two thirds for diazepam) filled by retail pharmacies in 1972 (Greenblatt & Shader, 1974). Given the cost and potentially hazardous effects of drug intervention, a clear need exists for an effective, nonpharmacological alternative. The present article reports the initial studies in a planned series of investiga-

tions focusing on behavioral intervention strategies for general tension.

Progressive relaxation training (Jacobson, 1938) has an extensive history of clinical application both as a primary treatment strategy for numerous disorders and as a component in the systematic desensitization of phobias (Wolpe, 1958). Even though well-controlled studies in the latter area are common, internally valid designs in the former are infrequent. A review of the literature reveals some cause-and-effect evidence for the progressive relaxation treatment of insomnia (e.g., Nicassio & Bootzin, 1974), childhood asthma (Alexander, 1972; Alexander, Miklich, & Hershkoff, 1972), hypertension (Deabler, Fidel, Dillenkoffer, & Elder, 1973; Shoemaker & Tasto, 1975), tension headaches (Cox, Freundlich, & Meyer, 1975), and phobias (Mathews & Gelder, 1969). Encouraging data from these tension-related problems suggest that relaxation training may be an efficacious procedure for less severe, but more pervasive, daily tension problems in the general population.

Experiment 1 is based on a senior honors thesis conducted by the third author. Both experiments were supported by Grant MH-27484 awarded to the first author from the National Institute of Mental Health and were presented, in part, at the meeting of the Midwestern Psychological Association, Chicago, May 1977.

Normative Data

A questionnaire administered to college students at the university in the fall and spring of 1975-1976 revealed that 21.2% typically felt tense 50% or more of each day. For subjects from the spring semester ($N = 479$), percentage of daily tension ratings correlated with tension severity ($r = .35$), the social items of Geer's (1965) Fear Survey Schedule ($r = .28$), and Mandler, Mandler, and Uviller's (1958) Autonomic Perception Questionnaire ($r = .27$). Scores on another problem (sleep disturbance) correlated with neither the tension items nor the other measures ($r_s < .07$), suggesting that more than response set to report problems contributed to the relationship between tension ratings and other anxiety-related problems.

Among students for whom tension represents an adjustment problem, specific stressors are readily identified as major contributors to their daily tension. In the first study reported below, subjects filled out daily questionnaires asking them to attribute the day's tension to one or more of six situational factors or to a seventh, "unattributable source," category. Over a 4-week period, the majority of specific tension was attributed to social situations (24.2%), followed by class work (14.5%), tests (14.5%), occupation (4.3%), and public speaking (1.4%); 23.5% was attributed to idiosyncratic sources, whereas the source of the tension was unidentifiable for only 16.7%.

A sizable population of individuals thus exists for whom tension is a daily problem attributable to their student occupation. Prior to committing resources to large-scale outcome studies, we investigated two methodological matters relevant to the use of this target behavior.

Experiment 1

The confounding influence of demand characteristics and suggestions of improvement on measures of behavioral change has become a crucial issue in outcome research (Borkovec, Weerts, & Bernstein, 1977). Unless evidence is obtained that outcome data do not reflect demand/suggestion effects, the internal validity of the study is seriously undermined. The problem is particularly critical for self-report

measures so susceptible to distortion and unreliability. Use of a placebo condition, traditionally regarded as a control for nonspecific effects, has been considered a sufficient methodological device for eliminating the demand confounding. Yet, recent empirical studies indicate that placebos may not establish a level of demand equivalent to that inherent in therapy conditions (cf. Kazdin & Wilcoxon, 1976). By implication, type of no-treatment condition may have a systematic influence on target behavior reports in a similar way. Usual waiting-list conditions may contain subtle demands for improvement during the waiting period or may provide sufficient attention and positive expectancies that actual improvement takes place (Goldstein, 1960). Subjects explicitly informed of their control group status with no mention of future treatment may not be exposed to the same demands or suggestions. In an early attempt to address this issue, Paul (1966) found greater anxiety reduction at follow-up assessment among waiting-list subjects relative to a no-contact control condition. Experiment 1 assessed the effects of demand for improvement and type of no-treatment condition on daily tension reports and provided a pilot evaluation of the effects of relaxation on this problem.

Method

Subjects. Subjects were selected from introductory psychology classes on the basis of two questions on a group testing questionnaire: (a) a 21-point rating scale (0% to 100%) of the percentage of the day they typically felt tense and (b) a 5-point scale (very mild to severely tense) of the severity of that tension. Subjects indicating at least moderate tension for 50% or more of the day were interviewed, given a packet of daily questionnaires, and randomly assigned to four conditions: waiting list or informed control under demand or no-demand instructions for improvement. Of the 53 subjects obtained, 10 were excluded in the final analysis due to voluntary termination, incomplete data, or low baseline severity. Thus, 43 subjects (9 in each waiting-list condition; 11 in the informed-control, demand condition; 14 in informed-control, no-demand condition) completed the study and received course credit for their participation.

Procedure. Subjects filled out a daily tension questionnaire each night before retiring throughout the 6 weeks of the study. The items were identical to the 6 weeks of the study. The items were identical to the group test scales (percent tense and severity ratings). At the time of initial interview, waiting-list subjects were told that 4 weeks of baseline information were first needed. Informed-control subjects were told that

they were in a control group and that their 6 weeks of data would be compared to a therapy group. Within each of these no-treatment groups, demand subjects were informed that research had shown self-monitoring of a problem to result in a reduction of the problem and that they could expect such a reduction to occur in their tension level and severity. Subjects in the no-demand condition were not informed of any potential effects of the self-monitoring.

Waiting-list subjects began treatment after the 4 baseline weeks. Sessions were held either in groups of five or less or individually, depending on scheduling possibilities. Progressive relaxation followed procedures by Bernstein and Borkovec (1973), except that training was presented by a single tape, providing only two tension-release cycles for each muscle group with no provision of additional cycles if tension remained. The first two sessions dealt with 14 muscle groups, and the last two sessions involved a four-muscle-group combination procedure. The tapes were made by the first author. Relaxation was described to the subjects as a skill involving (a) systematic tension release of gross muscle groups to reduce tension and autonomic arousal and (b) learning to identify and relax away extant tension. The importance of daily practice and frequent application was emphasized. After the first session subjects were instructed to practice twice daily (once during a particularly tense time) and to apply the procedure as frequently throughout the day as tension was identified.

Two undergraduate assistants served as training leaders, providing a demonstration of tension-release procedures, answering questions, and starting the taped procedures.

Results and Discussion

Subjects' scores on each of the two questionnaire items (percent tense and severity rating)

were averaged for each of the 4 baseline weeks and the 2 therapy weeks. Table 1 presents the resulting means for each condition.

Baseline phase. A three-way repeated measures analysis of variance (Demand \times No Treatment \times Weeks) on the percent tense measure during the 4-week baseline revealed no effects due to demand or no-treatment factors. The main effect of weeks, $F(3, 117) = 4.49$, $p < .01$, indicated that the percent tense ratings declined during the first 3 weeks (M over weeks = 44.33, 40.05, 36.07, and 37.08). Analysis on the severity data revealed a decline over weeks, $F(3, 117) = 5.01$, $p < .01$ (M s = 2.92, 2.67, 2.62, and 2.59), and a main effect of demand, $F(1, 39) = 5.49$, $p < .03$. Subjects given no demand for improvement reported less tension severity ($M = 2.55$) than did demand subjects ($M = 2.86$).

With one exception, the results indicate that whether or not a subject expects future treatment and whether or not he/she is told to expect improvement have little effect on several weeks of tension ratings. In the one case of a demand effect, the results were opposite to those commonly found in investigations of phobic behavior (Bernstein, 1973). Both percent tense and severity scores declined over weeks. Since spring vacation occurred during the 3rd and 4th weeks, it is unclear whether self-monitoring or a less tension-producing environment was primarily responsible for this decrease.

Table 1

Mean Self-Report Tension Scores for Waiting-List and Informed-Control Groups Under Demand and No-Demand Conditions During Baseline, Treatment Weeks, and Follow-up: Experiment 1

Measure	Group	Condition	Baseline week				Treatment week		Follow-up
			1	2	3	4	5	6	
% tense	Waiting list	Demand	51.4	39.8	40.1	40.9	36.0	30.0	33.2
		No demand	40.2	35.5	29.8	37.4	34.9	26.0	
	Informed control	M	45.8	37.7	34.9	39.2	35.4	28.0	
		Demand	45.2	43.2	39.7	39.5	52.8	54.0	
		No demand	40.5	41.7	34.7	30.4	42.0	37.1	
		M	42.8	42.4	37.2	35.0	47.4	45.5	
	Waiting list	Demand	3.1	2.6	2.7	2.8	2.7	2.5	46.3
		No demand	2.7	2.6	2.3	2.6	2.5	2.3	
Severity	Informed control	M	2.9	2.6	2.5	2.7	2.6	2.4	
		Demand	3.0	2.9	2.9	2.8	3.1	3.0	
		No demand	2.9	2.6	2.6	2.2	2.8	2.6	
		M	2.9	2.7	2.7	2.5	2.9	2.8	

Treatment phase. During treatment, the waiting-list group received relaxation training, and the informed-control group continued as a no-treatment group. With one exception, Treatment \times Demand analyses of variance indicated that the groups did not differ on either dependent measure at the 4th week, the final week prior to relaxation training ($p > .10$). The exception was that no-demand subjects reported less severity than demand subjects, $F(1, 39) = 5.53$, $p < .05$. Three-way repeated measures analyses of variance (Treatment \times Demand \times Weeks) on the 4th, 5th, and 6th weeks found significant Treatment \times Weeks interactions for both the percent tense data, $F(2, 78) = 11.61$, $p < .001$, and the severity data, $F(2, 78) = 8.92$, $p < .001$. On both measures, waiting-list subjects receiving relaxation training continued to decline, whereas informed-control subjects returned to their early baseline level, suggesting that the baseline decline for the total group was due to spring vacation and not to self-monitoring. Subjects given no demand for improvement during baseline continued to report lower levels of tension severity during the therapy period ($M = 2.49$) than demand subjects ($M = 2.82$), $F(1, 39) = 4.67$, $p < .04$.¹

After 7 months, subjects contacted by phone were asked to estimate current, typical percent tense and severity. Although differences were not significant due to large variability, the reports indicated maintenance of improvement among the 14 subjects contacted in the treated, waiting-list condition (M percent tense = 35.8, $SD = 25.3$; M severity = 2.57, $SD = .65$) and maintained baseline levels among the 19 subjects contacted in the informed-control condition (M percent tense = 45.8, $SD = 24.3$; M severity = 2.95, $SD = .91$). The earlier demand condition had no effect on the follow-up reports.

The results from the treatment phase suggest that specific or nonspecific ingredients in relaxation training may provide an effective form of brief intervention for daily tension problems, whereas follow-up indicated maintained improvement for most treated subjects. This conclusion is tentative, since presence or absence of relaxation training was confounded with type of no-treatment condition.

Experiment 2

The second experiment was designed to replicate the relaxation effect on reported tension under more controlled conditions and to initiate efforts to determine the active ingredient(s) within the progressive relaxation procedure.

Although Experiment 1 suggested minimal impact of demand/suggestion on daily tension reports, placebo and Demand \times Treatment interaction effects remained viable hypotheses to explain the outcome improvement. In addition to problems mentioned earlier about the ability of placebo conditions in therapy research to control for client expectancy and demand, the extended use of placebos with suffering individuals raises ethical issues, and alternative control procedures should be explored (O'Leary & Borkovec, in press). One such method, developed in our sleep disturbance program, involves counterdemand instructions: Subjects are told not to expect improvement until after a certain number of training sessions and weeks of practice, since past research has shown that this degree of training and application practice is required before noticeable effects can occur. Statistical comparisons among conditions are then made prior to the end of this counterdemand period. Expectation and demand are hypothetically held neutral during this period, allowing detection of active treatment effects relative to control conditions. The sleep studies have validated this function of the counterdemand procedure (cf. Borkovec & O'Brien, 1976). In Experiment 2, therefore, the counterdemand strategy was used instead of the traditional placebo condition to provide self-report data uninfluenced by main effects of expectancy and demand or their interaction with treatment.

Progressive relaxation consists of two principal procedural components: tension release of gross muscle groups and focused attention on the resulting sensations of tension and relaxation (Bernstein & Borkovec, 1973; Paul, 1966). A 2×2 design involving the

¹ Both dependent measures (percent tense and severity) were also analyzed by Treatment \times Demand \times Weeks analyses of variance with all 6 weeks included. Significant effects identical to those reported above emerged, and no additional effect was found.

presence or absence of each component thus defines the critical comparison conditions for isolation of the active ingredients of the procedure. Over the past 4 years, we have compared progressive relaxation to each component control condition in the treatment of sleep onset disturbance. This set of studies has allowed specific conclusions regarding both the active ingredients of relaxation treatment as well as the maintaining factors of the disturbance itself. Our goal in the present series is to replicate these component comparisons on the general tension problem. Experiment 2 involved the initial comparison between progressive relaxation and relaxation without muscle tension release.

Physiological data were collected during treatment for two reasons: (a) Such data would be useful for identifying the effective mechanism of relaxation treatment of tension, and (b) the study provided an opportunity to carefully assess the physiological effects of progressive relaxation. A review of the existing literature on the physiological effects of relaxation revealed equivocal findings (Borkovec & Sides, in press). Fifteen studies have found relaxation to be superior to control conditions, whereas 10 studies have revealed no differences. The two sets of studies differed significantly on two critical procedural details. Studies demonstrating relaxation superiority involved a greater number of sessions and more frequently used "live" rather than standardized taped instructions. Even though taped training removes a confounding therapist variable, subject control over training progress, an essential aspect of clinical use of the technique, is precluded and may be the reason for the superiority of live training.

In comparing progressive relaxation to relaxation without tension release, therefore, Experiment 2 included nine training sessions (essentially the full course of training recommended by Bernstein & Borkovec, 1973, for clinical use). Second, taped training was used, but by means of two cassettes and subject control over alternation between tapes, subjects controlled their own progress in treatment. Thus, the sessions were identical to the procedure followed in live therapy, but the potentially confounding factors of therapist characteristics and therapist bias were removed.

Finally, typical clinical use of progressive relaxation training involves a progression over sessions from some number of muscle groups to combinations of those muscle groups and ultimately to a recall phase without muscle tension release (Bernstein & Borkovec, 1973). In the latter procedure, the subject presumably learns to quickly and efficiently relax by recalling how the muscle groups felt previously when tensed and released. The clinical assumption of generalization of relaxation over such a progression of increasingly efficient procedures has never been tested. Physiological recordings for progressive relaxation subjects, therefore, occurred during the first training session involving the 14-muscle-group tension-release procedure, during the seventh session involving the 4-group tension release, and during the ninth session involving the 4-group recall procedure. A within-group test of transfer to the recall procedure was thus provided. Second, the inclusion of the relaxation without tension release condition and similar physiological assessments allowed comparisons at Session 7 between tension release and no-tension-release relaxation, and at Session 9, providing a between-groups test of the role of tension release pretraining on relaxation by the recall method. Since the same tape was used for both groups during Sessions 8 and 9, the groups differed only in terms of the presence or absence of tension release training during the initial seven sessions.

Method

Subjects. A new group of 36 undergraduates from introductory psychology were selected on the basis of their responses to three tension items on the group testing questionnaire (50% or greater daily tension, moderately severe or greater, and desire to receive treatment for tension problems). Subjects were randomly assigned within blocks of percent tense levels to three treatment conditions: progressive relaxation with tension release (TR), relaxation without tension release (NTR), and no treatment (NT). Subjects received course credit for participating, but they were not informed of the credit until they made a firm commitment to volunteer for the sake of therapeutic benefit. Although no assessment was made of the degree of their awareness of relaxation techniques, it was assumed that the subjects were relatively naive, since treatment was concluded prior to their introduction to psychotherapy and behavior therapy in their introductory class.

Experimenters. Three graduate students in clinical psychology served as the session leaders and were

counterbalanced across treatment conditions. Two undergraduate assistants served as polygraph technicians and session leaders for make-up sessions.

Dependent measures. All subjects filled out, just prior to retiring at night, a daily questionnaire asking for percent tense ratings, severity ratings, and a self-obtained 60-sec pulse rate. Daily ratings began at least 1 week prior to the first session and ended 1 week after the last session.

Therapy conditions. Subjects in the TR and NTR conditions received nine taped training sessions in their respective procedures over a 5-week period. The NT subjects came to the laboratory for "physiological assessment" sessions temporally corresponding to Sessions 1, 7, and 9 for treated subjects. Subjects in each condition were run in pairs during these recording sessions, whereas treated subjects were trained in groups of six during Sessions 2, 3, 4, 5, 6, and 8. During all training sessions, the group progressed through the procedures at the rate of the slowest subject.

1. Progressive relaxation. Subjects in TR received training in progressive relaxation as described by Bernstein and Borkovec (1973) with two modifications: a) Tensing foot muscles was excluded, and (b) there were only 9 sessions instead of 10. Sessions 1-3 involved 14 muscle groups; Sessions 4-5, a 7-group combination; Sessions 6-7, a 4-group combination; and Sessions 8-9, a 4-group recall procedure.

2. Relaxation without tension release. Relaxation training for NTR subjects was the same as that for TR, except subjects were instructed to identify any tension in each muscle group and to allow those muscles to relax. No actual tensing of muscles occurred, although the identical indirect suggestions of relaxation in TR were provided during each muscle group cycle. Muscle groups and their progressive combinations over sessions were identical to those in TR. During Sessions 8 and 9 (recall method for TR subjects), training tapes were identical for both therapy conditions.

3. No treatment. The NT subjects were told by phone that they would not be able to begin treatment until later in the semester but that they should continue to complete daily questionnaires.

Counterdemand manipulation. Treated subjects were told at the initial contact, after the first session, and daily in a written statement on their questionnaires that past research had shown that they would not notice any treatment effects until after the seventh session. At the eighth session, the session leader told the subjects that if they had been practicing conscientiously, improvement should become noticeable.

Physiological recording sessions. During Sessions 1, 7, and 9, physiological recordings were obtained on a Beckman R611 polygraph situated in an adjoining room. The measures included heart rate, respiration, and electromyogram (EMG) from the frontalis muscles of the forehead.

In Session 1, an introductory tape describing the rationale for the procedure was played, the session leader demonstrated the muscle groups involved, and the electrodes and strain gauges were attached. Two silver-silver chloride electrodes were attached to the

right and left sides of the chest for heart rate recording. Mercury strain gauges were taped across both the subject's chest and abdomen for respiration. Finally, three silver-silver chloride electrodes were attached to the subject's head, one each to the right and left frontal group for EMG and one in the center of the forehead as a ground. Electrode placement was followed by a 10-min adaptation period, during which the subjects were alone in the room and were instructed to lie quietly in recliner chairs with their eyes open. At the end of adaptation, the session leader reentered the room, and the training session began for TR or NTR subjects. NT subjects were asked to relax themselves for another 60 min with the experimenter absent from the room. Relaxation instructions for all nine sessions were presented to TR and NTR subjects via two cassette recorders: one containing instructions for two cycles of each muscle group and one containing repeated cycles, with both recorded by the first author. The session leader turned on the repeated cycles tape whenever a subject signaled remaining tension after two initial cycles, up to a total of four cycles as required. For NTR and TR subjects, 15-sec physiological samples were taken during (a) the last minute of adaptation, (b) the second relaxation cycle of the left biceps, the neck, and the right calf, and (c) for 1 min during the last min of the 2-min quiet period after training was completed. For NT subjects, samples were taken during the last min of adaptation and after the 15th, 30th, and 45th min of the 60-min period and during the last min of the session.

The procedure for Sessions 7 and 9 for TR and NTR subjects was the same, except that four-muscle group training required only about 10 min, and the 15-sec physiological samples were taken during the second relaxation cycle of each of the four-muscle combinations in addition to the adaptation and quiet period samples. For NT subjects the procedure was also similar to their first session, except that they were to relax themselves for only 10 min after the adaptation period, and 15-sec physiological samples were taken at the end of adaptation and at the 2nd, 4th, 6th, 8th, and 10th min of the self-relaxation period.

At the beginning and end of each recording session, subjects completed Husek and Alexander's (1963) Anxiety Differential. At the conclusion of Session 1, treated subjects completed Borkovec and Nau's (1972) therapy credibility questionnaire.

Results

Self-report outcome measures. Each subject's scores on each of the three daily questionnaire items (percent tense, severity rating, and pulse rate) were averaged for the pretherapy week, the week after the seventh session (counterdemand period), and the week after the ninth session (positive demand period). Table 2 presents the resulting means for the three treatment conditions on each self-report measure. One-way analyses of variance found

Table 2

Mean Self-report Tension Scores for Tension Release Relaxation (TR), Relaxation Without Tension Release (NTR), and No Treatment (NT) During Baseline, Counterdemand, and Positive Demand Weeks: Experiment 2

Measure	Condition	Last		
		Baseline	counterdemand	Positive demand
% tense	TR	52.6	40.0	35.8
	NTR	42.1	33.4	25.4
	NT	44.5	48.5	45.4
Severity	TR	3.0	2.8	2.4
	NTR	2.7	2.5	2.0
	NT	2.9	3.0	3.0
Pulse rate	TR	76.7	75.9	74.4
	NTR	75.5	72.1	72.9
	NT	67.7	68.7	70.1

no differences among the groups during the baseline week on the percent tense and severity data. A significant treatment effect was found on the pulse rate measure, $F(2, 31) = 4.37$, $p < .05$. Scheffé post hoc comparisons (Hays, 1963) indicated that neither TR nor NTR differed significantly from NT, although NT was significantly lower than the treated groups combined.

1. Counterdemand period. Two-way repeated measures analyses of variance (Treatment \times Weeks) were conducted on each questionnaire item from baseline to the seventh session. The Treatment \times Weeks interaction was significant only for the percent tense measure, $F(2, 31) = 5.12$, $p < .02$. Scheffé post hoc comparisons revealed that the combination of TR and NTR showed significantly greater reductions in tension than NT, whereas TR alone was significantly superior to NT; NTR did not differ from TR or NT. Covariance analysis applied to the pulse rate scores indicated no treatment effect.

2. Positive demand period. The same analyses applied to each measure from the baseline week to the week following the ninth session found significant Treatment \times Weeks interactions on all three measures, percent tense, $F(2, 31) = 6.69$, $p < .004$; severity, $F(2, 31) = 15.22$, $p < .001$; pulse rate, $F(2, 31) = 3.56$, $p < .05$. Covariance analysis of the pulse rate data revealed no treatment effect. Scheffé post hoc comparisons on the percent tense and severity measures indicated (a) no differences between TR and NTR and that (b) the two

treated groups, separately and combined, displayed significantly greater reductions than NT.

3. Frequency of practice, frequency of application, and treatment credibility. Three additional daily questionnaire items were completed by treated subjects once treatment was initiated: (a) frequency of formal relaxation practice during the day, (b) frequency of identifying daily tension and of attempting to apply relaxation to eliminate that tension, and (c) frequency of successful elimination of identified tension. Weekly averages of each measure and of the ratio of successes to attempted applications were submitted to a Treatment \times Weeks repeated measures analysis of variance. The main effect of treatment was significant on frequency of practicing, $F(1, 20) = 8.87$, $p < .008$. The practice frequency of TR subjects was close to the recommended twice-a-day schedule ($M = 1.78$), whereas that of NTR subjects was lower ($M = 1.43$). No effect emerged from analysis of the frequency of application, whereas the frequency of successful application increased significantly over weeks among the treated subjects, $F(6, 120) = 3.79$, $p < .002$. The ratio of successes to attempts also increased over weeks, $F(6, 120) = 13.89$, $p < .001$, with success incrementing from 44.7% after the first therapy session to 81.8% after the ninth session.

Credibility questionnaires (Borkovec & Nau, 1972) administered after the first session and after the final week of the study indicated that

the TR and NTR groups did not differ on reported confidence in their respective procedures. Correlations between credibility scores and improvement on the percent tense and severity measures during both counterdemand and positive demand periods were all nonsignificant.

Self-report process measures. Two-way repeated measures analyses of variance (Treatment \times Session) were applied to the Anxiety Differential scores obtained at the beginning and end of recording sessions (1, 7, and 9) and to the presession-postsession difference in Anxiety Differential scores. Only the main effect of weeks was significant on the presession measure, $F(2, 62) = 4.94, p < .02$. Subjects reported less anxiety at the beginning of the seventh and ninth sessions than at the beginning of the first session ($M_s = 71.1, 64.9$, and 66.0). On the postsession measure, the main effect of treatment was significant, $F(2, 31) = 5.09, p < .02$. The no-treatment group displayed the highest anxiety level at the end of the sessions, followed by TR and NTR ($M_s = 64.4, 59.2$, and 52.3 , respectively). None of the Scheffé pairwise comparisons were significant. Finally, the main effect of sessions was significant on the presession-postsession difference scores, $F(2, 62) = 3.26, p < .05$. The greatest decrements in anxiety occurred from the beginning to the end of the first session ($M_s = -11.9, -7.3$, and -6.5 for sessions 1, 7, and 9, respectively).

During treatment sessions, subjects in TR and NTR received two relaxation cycles on each muscle group before proceeding to the next group. Additional cycles were administered to any subject who signaled remaining tension. Over all nine sessions, the total number of additional cycles required to achieve reports of complete relaxation was 8.5 for the TR condition and 17.8 for the NTR condition, $t(22) = 2.10, p < .05$.

Physiological process measures. Physiological data were amplified on the Beckman polygraph, fed into a Hewlett-Packard FM tape recorder, and then reduced by a PDP-12 computer. Five respiration measures were derived from each sample: sec/cycle, sec/inspiration, sec/expiration, sec/inspiration to sec/expiration, and inspiration amplitude/expiration amplitude. Two cardiac measures

were obtained: heart rate in beats/min and heart rate variability. Too few EMG responses were recorded to allow meaningful analysis.

One-way analyses of variance conducted on the Session 1 adaptation period revealed no differences on any measure among the three treatment conditions prior to therapy. Three-way repeated measures analyses of variance were then performed. In addition to the treatment and session (1, 7, and 9) factors, these analyses included a phase factor with five levels (an adaptation sample, three muscle group samples, and a quiet period sample). The three muscle group samples had been obtained in Session 1 at the left biceps, neck, and right calf. Sessions 7 and 9, however, involved four muscle group combinations with samples taken after each group, (a) hands, forearms, and biceps; (b) face and neck; (c) chest and abdomen; and (d) thighs and calves. Consequently, the average of the latter two major muscle groups was taken for Sessions 7 and 9 to provide the third muscle group sample.

The only significant effect involving the treatment factor to emerge from analysis of the five respiration measures was a Treatment \times Phase interaction on the inspiration/expiration amplitude ratio, $F(8, 120) = 2.57, p < .05$. Inspection of Table 3 means indicates that inspiration amplitude, relative to expiration amplitude, increased for TR and NTR conditions from baseline to the first or second muscle group samples and then declined to near-adaptation levels. The NT condition

Table 3
Inspiration/Expiration Amplitude Means for Treatment Groups During the Five Phases of the Sessions

Phase	Group

3	1.06	1.05	1.08
4	1.01	1.03	1.02
Quiet Period			
5	1.01	1.03	1.01

Note. TR = tension release; NTR = relaxation without tension release; NT = no treatment.

showed a marked reduction in the ratio at the time corresponding to the first muscle group sample for treated subjects and a marked increase at the second sample before declining again below adaptation level.

No effects involving the treatment factor emerged from analysis of the heart rate data. Heart rate did decline from adaptation to quiet period for the total group ($M_s = 67.4$ to 65.0 , respectively), $F(4, 108) = 4.29$, $p < .01$. Heart rate variability declined initially and then rose during the five phases ($M_s = 4.9$, 4.0 , 4.7 , 4.7 , and 5.4), $F(4, 64) = 2.59$, $p < .05$.²

Correlations between physiological change and subjective improvement. To further assess the relationship between physiological activity and subjective tension, correlations for the total group of subjects were computed between physiological change during Sessions 1 and 7 and improvement in percent tense and severity scores during the counterdemand period (Sessions 1-7). Physiological change scores for each of the seven measures were obtained from the difference between the quiet period sample and the adaptation sample. Counterdemand improvement on percent tense was significantly related to four of the seven Session 1 change scores (sec/cycle, $r = -.57$; sec/expiration, $r = -.51$; sec/inspiration, $r = -.48$; heart rate variability, $r = -.36$). Thus, reduction in respiratory functioning and increased heart rate variability during Session 1 predicted outcome improvement on the percent tense measure. Only one correlation was significant between percent tense change and physiological change during Session 7 (sec/inspiration to sec/expiration, $r = .39$). Counterdemand improvement on the severity measure correlated significantly only with one Session 1 physiological measure (sec/cycle, $r = -.33$) and was not related to Session 7 measures.

Physiological relationships with improvement during the positive demand period were of little interest, since demand and expectancy effects may have contributed to outcome reports at that time. The fact that only one of the seven physiological measures (Session 1 heart rate variability) correlated significantly with improvement in percent tense ($r = -.39$) and severity ($r = -.42$) suggests that those positive demand outcome measures were indeed a function of nonphysiological variables.

Finally, although the self-reported pulse rate measure failed to reflect treatment effects due to pretherapy differences among the treatment groups, its potential usefulness in future research was supported by the finding that pretherapy pulse rate reports correlated significantly with continuously monitored heart rate during the adaptation period of Session 1, $r(26) = .46$, $p < .02$.

Follow-up contact. Ten TR and 7 NTR subjects were located 5 months later and phoned by a research assistant "blind" to their condition status. Subjects estimated current daily tension percentage, rated the severity of current tension and the effectiveness of their relaxation skill in reducing daily tension on 5-point scales, and indicated how often they used their relaxation skills during the 5-month period. Average percent tense scores were 24.0 for the TR condition and 20.3 for the NTR condition, indicating maintenance of the gains reported immediately at the end of treatment. Average severity ratings fell between "mild" and "moderate" levels of tension (2.70 for TR and 2.29 for NTR), representing slight though nonsignificant increases in severity since the end of treatment. The two treated groups did not differ significantly on either measure. On the third item, TR subjects reported being "quite" successful ($M = 4.10$, $SD = .74$) in applying the technique to eliminate tension, whereas the average success rating of NTR subjects fell between "very little" and "somewhat" ($M = 2.71$, $SD = 1.98$). Although the mean difference only approached significance (Mann-Whitney $U = 1.60$, $p < .12$), the variances of the two groups were significantly different, $F(6, 9) = 7.13$. Finally, TR subjects reported still practicing relaxation 2.11 times per week ($SD = 2.01$), whereas NTR subjects practiced only .55 times ($SD = .72$). The variance test was significant, $F(9, 6) = 7.77$, $p < .01$.

² Recordings from NT subjects during the first session were obtained for 60 minutes to guarantee that self-relaxation occurred at least as long as the TR and NTR sessions. Average duration of the first session for the two latter conditions was 36.0 minutes. All Session 1 physiological measures were therefore reanalyzed comparing TR and NTR to NT separately during its 30-minute, 45-minute, and 60-minute samples. No significant treatment effects were found for any measure at any of the three NT time samples.

whereas a Mann-Whitney test indicated that the group means also differed significantly ($z = 2.41, p < .02$).²

Discussion

The results of Experiment 2 lead more firmly to the conclusion that progressive relaxation can produce significant reductions in the daily tension experienced by overly tense individuals. The percent tense improvement was greater for treated subjects than for untreated controls. The fact that this difference was obtained during a counterdemand period suggests that some active ingredient within progressive relaxation procedures contributed to the subjective improvement that occurred, independent of demand, expectancy, and/or their interaction with treatment. Follow-up reports at 5 months indicated that these gains were maintained over a fairly long interval subsequent to treatment.

Although progressive relaxation differed significantly from no treatment during counterdemand, relaxation without tension release fell between the two latter conditions and differed significantly from neither. The critical procedural component in progressive relaxation was thus not unambiguously identified. Apparently, frequent attempts to relax while focusing on internal sensations are sufficient to promote tension reduction. Additional results, however, suggest a potentially important role for muscle tension release. Subjects in progressive relaxation required significantly fewer training cycles to produce subjective reports of complete relaxation. This result suggests that tension release relaxation may be a more efficient procedure and perhaps explains the absence of differences between the two treatment conditions on the during-session Anxiety Differential. Furthermore, progressive relaxation subjects practiced their procedure significantly more often both during treatment and over the succeeding 5 months.

Although it is unclear which aspect of tension release procedures accounts for these results, frequent practice of an adaptive skill is obviously desirable. Finally, perhaps due to the additional practice, progressive relaxation subjects tended to report greater success, with significantly less variability, in eliminating

daily tension 5 months after treatment. All of these differences, due to the presence or absence of muscle tension release, occurred between conditions that did not differ in credibility or the amount of improvement expected.

Our review of the literature had suggested that the present study maximized the probability of obtaining significant physiological reduction effects: several sessions, subject controlled treatment, and a presenting problem with some significance for daily adjustment. The absence of treatment effects on physiological process leads to two separate observations. First, the main difference between our procedures and those of previous studies finding significant relaxation effects (Borkovec & Sides, in press) was the presence or absence of a therapist. We are forced to conclude that the therapist factor may be a critical variable in promoting physiological reduction during relaxation training. Second, the fact that some relationships were found between physiological process and subjective improvement suggests that the subject's ability to reduce physiological activity by any procedure, including self-relaxation, does contribute to reductions in subjective tension. However, the treatment effects on the subjective outcome measures indicate that such improvement will occur only if the subject realizes that relaxation is a skill to be practiced and applied to his/her daily life.

Hopefully, future experiments involving comparisons of progressive relaxation with other component control conditions will further elaborate the mechanisms by which relaxation promotes reductions in daily tension. With such specifications, it should be possible to develop increasingly efficient and efficacious procedures for ameliorating a pervasive adjustment problem.

² After the conclusion of the treatment period of the study, NT subjects were given similar progressive relaxation training with three exceptions: (a) No physiological recording was conducted, (b) no counterdemand instructions were administered, and (c) subjects were not required to complete daily questionnaires during their treatment period. With these differences in mind, 5-month follow-up information obtained on 5 NT subjects indicated mean values generally similar to those of the TR subjects (percent tense = 27.5, severity = 2.80; effectiveness of application = 3.25; and frequency of practice = 1.45).

Behavioral Contingencies and Self-mutilation in Lesch-Nyhan Disease

Lowell Anderson, Joseph Dancis, and Murray Alpert
New York University School of Medicine

Lesch-Nyhan syndrome is a rare, sex-linked, recessive disease that is accompanied by severe self-mutilation, especially finger biting. Evidence is presented suggesting that parental response patterns may contribute to the genesis of the self-injurious behavior (SIB). The therapeutic effectiveness of punishment, positive reinforcement of either SIB or non-SIB, and time-out learning paradigms were evaluated. Electric skin shock failed to suppress the behavior. Positive reinforcement of non-self-injury and time-out from social reinforcement were consistently and rapidly effective, indicating a complex interaction of genetic and environmental factors in the production of SIB. Elimination or major reductions in incidence of SIB was maintained during follow-up periods of 2 years.

Lesch-Nyhan disease, which is characterized by hyperuricemia, stunting of growth, choreoathetosis, generalized spasticity, and compulsive self-mutilation, is a rare sex-linked genetic disease (Berman, Balis, & Dancis, 1969). The genetic mutation is responsible for a deficiency of hypoxanthine phosphoribosyltransferase activity, an enzyme involved in purine metabolism (Rubin, Dancis, Yip, Nowinski, & Balis, 1971; Seegmiller, Rosenbloom, & Kelley, 1967). Although mental retardation was originally thought to be a necessary concomitant of Lesch-Nyhan disease (Nyhan, 1968), another study described a child with the disease who had normal receptive intelligence (Scherzer & Olson, 1969). However, the children are severely impaired in motor function and are unable to walk or sit without support. Speech is dysarthric and difficult to understand.

The diagnosis is suggested by the symptomatology associated with excessive urinary excretion of uric acid and is confirmed by

demonstrating the specific enzyme defect in red or white blood cells or skin fibroblasts. Family patterns of inheritance and mosaicism in tissues of the obligatory heterozygote (Migeon, Der Kaloustian, & Nyhan, 1968; Silver, Cox, Balis, & Dancis, 1972) indicate an X-linked recessive disease. Management strategies are supportive of kidney function by preventing excessive production of uric acid with allopurinol, thereby greatly increasing life expectancy. Questions concerning procedures for managing the behavioral consequences of the illness and for optimizing the life adjustment of these children thus become relevant.

One of the most striking and disabling characteristics of the disease is a pattern of self-injurious behavior (SIB) that affects virtually all Lesch-Nyhan children (Lesch & Nyhan, 1964). Near the end of the second year of life, they begin to bite their fingers, lips, or arms with sufficient force to cause lacerations, expose tendons, and even amputate fingertips. If not prevented, SIB occurs at a very high rate, accompanied by general agitation and crying. Reliance on tubular arm splint restraints to prevent finger biting and extraction of teeth to prevent lip biting have constituted the only therapeutic approach to SIB in Lesch-Nyhan children.

Although no direct studies have been reported that demonstrate normal pain sensi-

This research was performed in the Clinical Research Unit of New York University School of Medicine in Bellevue Hospital and was supported by National Institute of Health Grant HDO 4526.

tivity, observers agree that pain thresholds do not appear to be elevated in Lesch-Nyhan children and that the children are manifestly distressed by the tissue damage. In fact, it is commonly observed that the children appear placid and passive while in restraints but become agitated and distressed if the restraints are removed. It also seems clear that the pattern of SIB in these children differs from the pattern of occasional and accidental injury sometimes reported in individuals with congenital lack of pain sensitivity.

In our preliminary investigations, using naturalistic observations and careful interviews with parents, a pattern of possible environmental support for the behavior began to emerge. The frequency of self-injury varied considerably and predictably with variations in the environment. For example, we recorded attempts at SIB in one child while he was cared for by his grandfather, his mother, and his grandmother. During a 15-minute period when the grandfather cared for the child, there were 110 attempts to self-injure on the first day of observation and 104 on another day. With the mother, the corresponding figures were 74 and 77, whereas with the grandmother there were "only" 10 and 12 attempts at self-injury. The chronological order of these observations was counterbalanced to exclude an artifact of a time trend.

The consistency of different response rates in the presence of different family members and the wide range of response rates among family members suggest a behavior that is under specific discrimination. Thus, although it is clear that the SIB is intimately related to the genetic defect, important environmental contributions may also be presumed. A series of studies were therefore initiated to identify the contingencies that supported SIB and to design an intervention to reduce the use of restraints.

Method

Subjects

Five males, C.S., P.B., C.W., R.K., and J.A., 3, 5, 11, 12, and 13 years old, respectively, were studied while they were inpatients in the clinical research unit of New York University School of Medicine. All cases had been previously studied for extended periods, and the diagnosis had been confirmed by demonstration of

the enzymatic defect. The oldest patient was institutionalized, whereas the four younger ones lived at home. They demonstrated the characteristic motor retardation and spasticity and could not sit or stand without support. Prior to treatment the children wore arm restraints and bore scars on fingers and lips. Upon removal of restraints, they would immediately become agitated and begin finger biting with an intensity that would lead to severe injury in a matter of minutes. In addition to finger biting, other SIB such as lip biting, head banging, or neck snapping were present in all children.

Despite the fact that all were severely impaired in verbal expression and motor control, it was our impression that the receptive intelligence of these five children ranged from mildly retarded through normal. Because of their extremely poor verbal and motor abilities, attempts to administer intelligence tests were either not undertaken or produced scores that seemed far too low to be a valid indication of IQ. However, the children are responsive to social situations and to speech. Three of the children can count, tell time, and have memorized the television schedule. At times, they seem to speak in sentences, although none can read. The unusual nature of the disease makes it difficult to accurately evaluate their intelligence, but they are not severely retarded.

Written informed consent was obtained from both parents of all children, and our procedures were approved by the Medical Center's Human Research Committee. Parents and therapists experienced the shock levels delivered to the children.

Procedure

Four learning paradigms were investigated in all children—punishment, positive reinforcement of non-SIB by noncontingent attention, positive reinforcement of SIB by contingent attention, and time-out contingent on self-injury. These paradigms were compared to a response prevention baseline. Overriding clinical considerations prevented us from adhering to a rigid research design. Number of learning trials, sessions, and order of investigation of learning contingencies varied slightly from child to child. The specific information provided in Figure 1. Throughout the study, two independent raters recorded the number of attempted SIBs. Observer reliability was found to be good (Pearson $r = .94$).

Response prevention. The child was seated in a wheelchair, and his arms were released from the restraint. An assistant, seated in front of the child, intercepted the child's hand as it approached his mouth and placed it back in the child's lap without speaking or otherwise interacting with the child.

Punishment. Subjects C.S., P.B., C.W., and R.K. were given electric finger shock contingent on each hand-to-mouth contact. The fifth child, J.A., was given shock contingent on attempts at head banging. Shock was delivered by a Scientific Prototype isolated shock source (102K) through electrodes attached to the fingers of the hand that was most frequently bitten. In all cases the shock intensity was 3 mA, a level generally described as quite painful but well below that which

Figure 1. Self-injurious behavior (SIB) during therapeutic intervention and at follow-up. (Left side of chart indicates frequency of SIB during 30-minute treatment sessions administered by therapist. Right side of chart records time spent in restraints at home and in school, at follow-up. Pos. Reinf. = positive reinforcement. CS, PB, CW, RK, and JA are the initials of the subjects.)

reduces tissue damage. The response prevention procedure was used concurrently with finger shock.

Positive reinforcement of non-SIB by noncontingent attention. When the child was not agitated or attempted to bite, the therapist would smile, talk, play, or in other ways interact with the child.

Reinforcement consisted of verbal reinforcement ("good boy," "you're doing fine," etc.) and stroking the head, patting the head, and so forth. The first session began with the removal of one arm restraint. The therapist used the response prevention procedure to prevent injury and would hold and stroke the arm and maintain conversation only during periods of calm. Usually, reinforcement was given for very brief periods of calm behavior and gradually developed into longer intervals. After biting had been eliminated for intervals of several minutes, the second arm restraint was removed.

Positive reinforcement of SIB by contingent attention. The purpose of this approach was to evaluate, under laboratory conditions, the effect of the management commonly used by parents in the home. The therapist responded to each attempted SIB with a quick intervention to prevent injury while making reassuring

statements and stroking the child. Non-SIBs were ignored.

Time-out contingent on SIB. Time-out consisted of the withdrawal of all attention to the child following each SIB attempt. As the hand began moving toward the mouth, the therapist simply turned away from the child for about 5 sec. The response prevention procedure of intercepting hand-to-mouth contacts was discontinued.

Results

Figure 1 presents the rate of SIB attempts by each child for each of the treatment modalities in which that child participated. Each bar represents the data from three $\frac{1}{2}$ -hour sessions. Usually three sessions were conducted each day. Note the relatively constant level of SIB under baseline conditions. In all cases punishment failed to suppress the frequency of SIB and, in fact, it appeared to act as a facilitator.

Figure 2. The effect of noncontingent attention, contingent attention, and time-out frequency of self-injurious behavior (SIB) in 12-year-old Lesch-Nyhan child R.K. (Each point represents the mean hand-to-mouth contact per minute in a 5-minute observation period.)

The rate of self-injury ranged from 5 to 14 per minute, making the total number of learning trials for each 30-minute "punishment" session substantial.

Positive reinforcement for non-SIB produced a decrease in the attempts for Subjects C.S. and C.W. but not for R.K. The procedure was not tried with Subjects P.B. and J.A. Time-out was associated with a decrease in SIB for Subjects P.B., C.W., R.K., and J.A. but was not tried with C.S. With the exception of Subject R.K., for whom the procedure was not used, the combination of time-out with positive reinforcement of non-SIB eliminated self-injury in all cases.

The results of positive reinforcement of SIB by contingent attention are presented in Figure 2. This procedure was used with the 12-year-old child (Subject R.K.) and was conducted prior to therapeutic training. On Day 1, the child was given 1 hour of noncontingent attention (reinforcement of non-SIB), 40 minutes of attention contingent on self-injury (reinforcement of SIB), and 1 hour of time-out. On Day 2, the order of the time-out and noncontingent attention procedure was reversed. For each of the 2 days, the sessions were continuous with no pause between manipulations. Each data point represents the mean number of finger- or lip-biting responses per minute for blocks of 5-minute observations averaged over the 2 test days. Both noncontingent attention (reinforcement of other behaviors) and time-out contingent on self-injury resulted in virtual elimination of self-injury. Positive reinforcement of SIB by giving attention contingent on self-injury, however, produced a rapid and dramatic increase in the rate of finger and lip biting.

An extinction curve can be observed that extends into the early minutes of the time-out period (following termination of the 40-minute period of contingent attention). The reinforcement by contingent attention period, originally planned for 1 hour, could not be completed because the SIB occurred with increased rate and force and the therapist was unable to respond quickly enough to prevent damage.

Figure 3. Effects on self-injurious behavior for Subject J.A.

Figure 3 contains a summary of the results during procedures intended to differentiate the influence of positive reinforcement by contingent attention intrinsic to response prevention from the effect of shock. Prior to therapeutic training, response prevention alone, response prevention plus finger shock (3 mA), finger shock alone, and time-out were investigated in Subject J.A. Four 15-minute observations were made each day for 6 consecutive days. Each manipulation was studied during three of these observation periods. Response prevention was used as a baseline against which the effects of the other procedures were assessed. Thus, the response prevention baseline procedure both preceded and followed each of the other manipulations. This child was selected for this investigation because his teeth had been extracted and it was possible to eliminate the response prevention procedure without fear of serious damage. Each data point represents the rate of SIB per 5-minute period.

The response prevention procedure was evaluated four times during the 6-day test. On each occasion there was a consistent and relatively stable rate of between four and seven attempts at self-injury per minute. When shock was administered without interrupting the behavior (response prevention discontinued), the self-injury rate remained at about the level of the response prevention "baseline." When shock and response prevention were combined, the rate increased to almost twice that of either procedure alone. Time-out produced a rapid decrease in SIB to less than one per minute.

Generalization Training

Following elimination of SIB by time-out and positive reinforcement of non-SIB behavior, additional therapists were introduced in sequence. In all cases, by the fifth therapist, the generalization process was complete and SIB was eliminated in the presence of all hospital personnel. Parents were then brought to the hospital and trained in the use of time-out and positive reinforcement of non-SIB procedures. The parents received 1-3 days of training. The training was then transferred to the home, and, depending on the ease of

training, the therapist visited the home for 3-7 days.

Follow-up

The follow-up period ranged from 22 to 24 months. During this time, a therapist was available, on request, for home visits to analyze difficulties and refine the therapeutic skills of the parents. Rarely, however, did the therapist directly intervene in a behavioral problem, limiting herself to advice and instruction. Most requests for additional assistance were not for recurrences of SIBs but for problems such as temper tantrums, breath holding, spitting, cursing, or other antisocial or noncompliant behaviors that had not been treated in the hospital.

For a 1-week period at the end of follow-up, each family was asked to record the daily frequency of SIBs during mealtimes, bedtime, and while bathing or changing diapers. The parents also recorded the total amount of time their child spent in and out of restraints and the conditions surrounding the use of restraints.

The youngest child (C.S.) was without arm restraints for 18 months following discharge, at which time the parents decided to use them occasionally during high-risk periods (defined as when the child was "cranky," tired, or during automobile rides). It appeared that restraints were easier for the parents than the constant vigil required to maintain appropriate contingencies. Most recurrences of self-injury could be attributed to a specific event such as an untrained grandmother moving into the house or the illness of the mother necessitating a radical change in the daily routines.

SIB has been almost completely absent in the school setting. The rating form revealed that on the average, the child was in restraints 5% of the day. No incidents of self-injury were noted during the rating period, although the mother used the time-out procedure approximately three times per day to interrupt threatened finger biting. At bedtime the child was placed in restraints.

The 5-year-old subject (PB) remained free of arm restraints in school. At other times restraints were used under specific circumstances such as the bus ride to and from school. The behavior was under a high degree of

stimulus control. With certain adults or specific settings, SIB did not occur. During the 1-week period when the rating form was in use, the child was in restraints 12% of the day, and self-injury in the form of biting the inside of the mouth occurred, on the average, twice per day. At bedtime the child was placed in restraints.

The 11-year-old subject (CW) has remained free of restraints while at school and at bedtime. At home he remained free of restraints for 6 months following treatment, at which time he was placed again in arm braces by his parents. The failure to maintain the gains in the home coincided with the development of a chaotic situation following the hospitalization of the mother and the inability of the father to care adequately for the child. One finger-biting event was recorded in the final week of follow-up, but there were numerous instances of head snapping. He was in restraints approximately 39% of the day.

The 12-year-old subject (RK) remained completely free of restraints during the day but was placed in elbow braces at bedtime. This child has never engaged in SIB during the night, and the restraints seemed more related to parental habit than necessity. No SIBs were recorded during the 1-week period when the rating form was in use.

The oldest boy (JA), who is institutionalized at a state school, has been without restraints for the entire follow-up period. His teacher and a nurse's aide with primary-care responsibilities for the child have responded independently to the questionnaire and to personal interview. Neither have reported the need of either day or night restraints and neither are aware of any recent attempts at self-injury. A physical examination of the child did not reveal any signs of recent self-injury.

In summary, there has been a considerable reduction in the dependence on restraints for all of the children. With two children, arm restraints have been discontinued entirely during the day. For another two, the restraints are applied at infrequent intervals, usually in response to the parent's wish to temporarily end the need for maintaining appropriate contingencies rather than to treat SIB. The fifth child, after 6 months free of restraints, is now in arm splints almost half of the day. This

is undoubtedly related to a turbulent home situation, with both parents being invalids and with the child having unruly siblings. Most important to educational and social development, the children are usually free of arm restraints in school. At night three of the five children are placed in restraints.

Discussion

To conduct an operant conditioning analysis without permitting self-injury, a response prevention procedure was instituted. Following removal of the restraints, a therapist seated in front of the child interrupted movement of finger to mouth just before injury could be inflicted. The frequency of such movements provided the baseline against which to measure the effectiveness of a variety of interventions.

Because of the reported effectiveness of the punishment paradigm in the alleviation of SIB associated with other diseases (Lovaas & Simmons, 1969), electric shock administered to the fingers was the first conditioning modality that was tried. In most instances, there was an increase in finger-to-mouth movements (Figure 1). The increased rate of SIB attempts was attributed to the effect of shock superimposed on the response prevention procedure. Separate analysis of these two components was possible in J.A., whose teeth had been previously removed to prevent finger biting. Shock and response prevention were roughly equivalent in their ability to maintain the rate of SIB (Figure 3). The unexpected ineffectiveness of aversive stimulation contrasted with the rapid and consistent success in eliminating self-mutilation using time-out and positive reinforcement of non-SIB. There did not appear to be any replacement of SIB with other undesirable behaviors. Spitting and cursing were common, but these behaviors usually antedated treatment.

In other diagnostic categories, punishment has been found to be consistently and rapidly effective in reducing the rate of SIB (Butcher, & Lovaas, 1968; Corte, Wolfe, & Locke, 1971; Lovaas & Simmons, 1969; Risley, 1968; Tate, 1972; Tate & Baroff, 1966; Young & Wincze, 1974). Although failures to maintain the gains produced by contingent electric skin shock frequently occur (Harris & Romanczyk, 1976;

Jones, Simmons, & Frankel, 1974; Romanczyk & Goren, 1975), no report could be located that indicated a total ineffectiveness of the procedure. The failure of contingent shock to reduce the rate of self-injury thus seems to be peculiar to Lesch-Nyhan disease and may therefore be a clue to the action of the genetic defect and how it interacts with environmental experience to produce the behaviors characteristic of this disease.

Significant gains, as measured by freedom from arm restraints, were maintained in all children during an observation period of 2 years. The opportunity to attend school without restraints permitted participation in educational and social activities, making for happier children and easing tensions at home. The gains at home were also significant but were more irregular, indicating that either teachers can more reliably maintain the appropriate contingencies or perhaps a busy teacher, nurse's aide, or an unsuspecting stranger are less likely to attend to finger biting, thus creating a discriminative period for non-self-injury.

The maintenance of long-term improvement in general is better than that reported for SIB associated with autism, schizophrenia, or mental retardation (Harris & Romanczyk, 1976; Romanczyk & Goren, 1975). This may be related to the presumed higher intelligence of the Lesch-Nyhan child and the ability to participate in socially appropriate activities once freed of physical restraints. This ability to interact with their environment when not restrained, and the loss of that activity contingent on self-injury, may provide the necessary contingencies to account for the persistence of treatment effects.

It is evident from this study that the SIB of Lesch-Nyhan disease is strongly influenced by environmental factors. Contingent attention of SIB serves as a strong reinforcer (see Figure 2). Inexperienced attendants, such as parents and grandparents, are likely to react to SIB with contingent attention. On the other hand, when trained in time-out and appropriate reinforcement techniques, the same personnel can maintain elimination of the undesirable behavior. Although SIB must be associated in some way with the primary enzymatic defect of Lesch-Nyhan disease, a

deficiency in hypoxanthine phosphoribosyltransferase, it is not an inevitable consequence. The sequence of events leading to the establishment of SIB is not known, but its maintenance is dependent on environmental support.

In selecting children for this treatment, a careful analysis of the home situation and parental motivation is essential. Parents should be carefully trained and candidly warned of the difficulties they will encounter, and initiation of treatment should be postponed until the parents are able to make use of consultation. In training parents or therapists to administer this therapy, there are three treatment issues to be emphasized.

First and most important, in the early stages of training, time-out or isolation should be used with caution and only under the direction of a skilled therapist. Time-out is an extinction procedure, and therefore the schedule of reinforcement that has maintained the behavior is critically related to the rate of behavior change. Because of the constant vigilance that these children require, most SIB is maintained by almost continuous reinforcement. Behavior maintained on a high-density reinforcement schedule is the most amenable to extinction procedures, and it is important that this advantage not be lost. Care should be taken that self-injury is not reinforced during time-out or isolation, thereby increasing its resistance to extinction and accidentally rendering the time-out or isolation procedures ineffective. If parents or therapists have already trained a child to self-injure in the absence of direct visual contact, an abrupt change in the salient characteristics of the isolation situation or a gradual errorless learning procedure may prove helpful. It would be unwise to initiate therapy unless isolation can be made a discriminative period for non-self-injury.

Second, in designing continuing care procedures, it should be remembered that self-injury has proven to be an attention-eliciting behavior. The likelihood of maintaining good treatment effects depends heavily on the child's ability to gain attention in socially appropriate ways despite the extreme limitations on physical movement imposed by the spasticity. Self-help skills such as eating without assistance, arranging access to television, books, the out-of-doors, and so on, must be devised. Our

most successful cases had willing and capable parents as well as access to educational institutions in which training in self-help skills was emphasized.

Third, the results of this study suggest that Lesch-Nyhan children are either reinforced by, do not learn from, or are unable to inhibit a response associated with a "punishment" contingency. This effect is specific to punishment procedures in that the children can learn to inhibit a response when a time-out contingency is used. From the parents' point of view, it appears that any attempt to use discipline or punishment for any behavior (on close scrutiny, the range of inappropriate behavior is endless) is not only ineffective but frequently has the effect of increasing the rate of behavior. Inasmuch as discipline is a primary means of socialization and parental reliance on the technique is so pervasive, it is unreasonable to expect that the therapist's instructions can be adequately followed on a daily basis. Thus the procedures described above should be viewed as management techniques for specific behaviors (e.g., finger or lip biting) occurring in specific situations (e.g., physical therapy or other formal educational experiences) and not as a general cure for the manifold behavioral problems associated with Lesch-Nyhan disease.

On the Decision to Be Assertive

Decky Fiedler

Lee Roy Beach
University of Washington

This study examines the applicability of an expectancy/decision model to assertiveness in a nonclinical population. Assertiveness, defined here as refusal to comply with an unreasonable request, has been researched extensively from the viewpoint of behavior theory, which prescribes anxiety reduction and skill acquisition for the training of assertive behaviors. However, little has been done to investigate the reasons why assertive behavior occurs in one situation and not in another. The results of this study suggest that participants, irrespective of their scores on standard measures of assertiveness and of anxiety, consider the consequences of being assertive when making a decision about how to behave. Moreover, it was found that the difference between participants who chose an assertive response and those who did not lies in the formers' assessments of the probabilities that bad consequences will occur and good consequences will not rather than in their evaluations of how bad or how good those consequences would be. These results imply that training programs should take into account the participant's perceptions of the risks involved in being assertive and that the focus should be on changing these perceptions rather than on attempting to change his or her values or focusing solely on specific assertive behaviors.

Studies of assertiveness and designs for assertiveness training programs have revolved around two hypotheses about why some persons tend to be less assertive than they might. One hypothesis (Wolpe, 1958, 1969; Wolpe & Lazarus, 1966) is that nonadaptive anxiety inhibits the expression of assertiveness. The second hypothesis (Lazarus, 1971) is that unassertive people lack the necessary skills for assertiveness. In practice, these hypotheses are not mutually exclusive and may occur simultaneously (Wolpe & Lazarus, 1966), but they are presented as such to highlight the most salient features of assertive behavior as described in each theory. To complement and extend these views, we propose a third hypothesis: Prior to acting

either assertively or nonassertively, people weigh the consequences that could be expected to result from either behavior and they elect the behavior that appears most favorable. That is, the decision to act assertively is not a general trait. Instead, it varies in any situation according to the consequences expected by the person involved. Differences between persons who tend in general to be assertive and those who tend in general to be less so lie in differences in their expectations about these consequences.

Assertiveness training programs are designed to help people who have problems with interpersonal communication as a result of overly passive or overly aggressive behaviors. Using techniques such as instruction, modeling, rehearsal, and feedback, training attempts to reduce the anxiety of interpersonal encounters and to teach specific behaviors such as appropriate eye contact, appropriate voice tone, use of "I" statements, appropriate body language, and so on. These programs have been successfully offered to a variety of clinical populations (e.g., Hersen, Eisler, & Miller, 1973).

This research was partially supported by the Office of Naval Research Contract N00014-76-C-0193 (Terence R. Mitchell and Lee Roy Beach, principal investigators).

The authors wish to thank Martha Perry, David Hathaway, and Diana Stacy, Robyn Hembree, and Lynn Bowen.

Even though there is evidence that as a result of decreased anxiety and acquired assertiveness skills, there are changes in both assertive behavior and self-report of assertiveness (McFall & Lillisand, 1971; Rathus, 1973), there are still theoretical difficulties. One difficulty is that if one adopts a very extreme interpretation of either of the original models, training that lowers anxiety or teaches skills should result in the trainee being rather consistently assertive in all subsequent situations that call for assertiveness. This, however, is patently not the case. One problem is that behaviors encouraged by training often are not rewarded, or are even punished, by others. A woman who is learning to be assertive may find that she was more highly valued when she was accommodating, self-denying, and quiet. Her assertiveness may increase her self-respect, but she may be unwilling to accept the reactions of others to her behavior and therefore cease to use her new skills. Even though in actual practice assertiveness trainers tacitly recognize this difficulty, neither a pure anxiety reduction theory nor a pure response acquisition theory approach can account for a subject's own evaluation of his or her response.

The second difficulty lies with the "lack of skills" hypothesis: There is evidence that unassertive persons *do* know the appropriate assertive responses. Gottman and Schwartz (Note 1) found that nonassertive persons did not differ from highly assertive persons in their ability to construct a written response or verbally deliver an assertive response in a hypothetical situation. The difference between the two groups of persons did not become apparent until they were confronted with a situation that was highly similar to an actual interpersonal confrontation. In short, nonassertive people may well know what to do, but in stressful or high-risk situations they tend not to do it.

Although both skill acquisition and anxiety reduction models explain some of the consequent behavior change experienced during assertiveness training, a cognitive approach can add to our understanding of this process by exploring the conditions under which a person will choose to act in an assertive manner and how that person

then evaluates his or her response. We propose therefore, that a person's willingness to be assertive, defined here as his or her refusal to comply with an unreasonable request, can be predicted from knowing how he or she evaluates the possible consequences of being assertive in various kinds of situations. What differentiates assertive and nonassertive persons is less a matter of their "personalities" or differences in their repertoire of skills than it is of differences in how they evaluate the consequences of being assertive in different kinds of situations. This hypothesis implies that if a person maintains a rather stable, say, negative, evaluation of a specific class of situations, it would be expected that he or she would characteristically be nonassertive in such situations but not necessarily in other situations. It is also likely to be true that in any interaction a person may evaluate the consequences of assertion to be negative due to the specific characteristics of the situation (who is involved, the timing of the response, past history of response with that individual, etc.). In a similar interaction with different topographical attributes, assertion may be perceived as the desirable response.

Decision/Expectancy Theory

Decision-expectancy theory provides a model for describing choice behavior. The basic assumptions are that people act in a fairly rational way and that their behavior is determined by their expectation that the behavior will lead to various consequences and their evaluation of these consequences (Mitchell & Biglan, 1971). Choosing the action that will result in the maximum expected long-range gain requires comparing the alternatives in terms of the decision maker's utility for each of the possible consequences and in terms of the decision maker's expectation that the action will result in the attainment of each of these outcomes; the action that promises the larger expected gain (or the least expected loss) is the one to be selected.

Actually, there are two similar but formally different models. The first, expectancy theory, as described by Fishbein and Ajzen (1975), is concerned with the relationships among

beliefs and values and behavioral intent (BI). BI is defined as the intention to perform a behavior, and its magnitude is assessed by obtaining the person's subjective judgment about whether or not he or she will perform that behavior. The attitude toward a behavior, and therefore BI, is related to the person's evaluation of potential consequences, measured on a 7-point bipolar affective dimension, and a similarly measured belief about the likelihoods that the consequences will occur. In the present case, a subject's evaluation of various consequences that could result from assertion would be multiplied by his or her belief that these will occur as a result of assertion. The sum of these products is added to a component that reflects relevant social pressures (usually obtained from ratings about the opinions of significant others, social norms, etc.), and this sum is assumed to be monotonically related to the magnitude of the person's intention to perform (BI) the assertive act in question.

The second model, subjective expected utility (SEU), comes from the area of decision theory (Edwards, 1954). It differs from the expectancy model primarily in its greater mathematical simplicity, but the logic is quite similar; when the person must decide between an assertive and a nonassertive course of action, he or she must evaluate these actions in terms of the utilities of their positive consequences (U), the utilities of their negative consequences (\bar{U}), and the subjective probabilities (P and $1 - P$) of these consequences occurring if one or the other course of action is selected.

$$\begin{aligned} SEU_A &= P_{1A}U_1 + P_{2A}U_2 + \dots + P_{nA}U_n \\ &\quad + (1 - P_{1A})\bar{U}_1 + (1 - P_{2A})\bar{U}_2 \\ &\quad + \dots + (1 - P_{nA})\bar{U}_n \\ SEU_{\bar{A}} &= P_{1\bar{A}}U_1 + P_{2\bar{A}}U_2 + \dots + P_{n\bar{A}}U_n \\ &\quad + (1 - P_{1\bar{A}})\bar{U}_1 + (1 - P_{2\bar{A}})\bar{U}_2 \\ &\quad + \dots + (1 - P_{n\bar{A}})\bar{U}_n, \end{aligned}$$

where A and \bar{A} represent the two classes of actions, assertive or nonassertive. SEU is equal to the sum of the utilities of the possible positive and negative consequences weighted by their probabilities of occurrence, and the person should select the action with the larger SEU. The social component of the expectancy

model is treated as just another utility in the SEU model, which is what makes the latter a simpler model. Merging expectancy theory and the SEU model yields the prediction that the greater the SEU for an action, the more the person should intend to follow that course of action (BI). This model has been applied to a number of areas including career decision planning (Holmstrom & Beach, 1973; Mitchell & Beach, 1977; Muchensky & Fitch, 1975), third-grade children's decisions to attempt academic tasks (Gray, 1975), and family-planning decisions (Townes, Beach, Campbell, & Martin, 1977).

This study examines women's intent to act or not act in an assertive manner in light of their evaluations of the possible consequences of the two behaviors and the amount of risk perceived to be involved in performing either behavior given the characteristics of the situation. The strength of BI is measured by the number of times the participant states her intent to refuse a series of unreasonable requests that are made in videotaped or written scenes involving a high or low status male or female antagonist. Separate judgments of utility and probability permit computation of SEUs for assertion and nonassertion; persons differing in BI should have corresponding differences in their SEUs.

Method

General Strategy

First, participants were administered an assertiveness test and an anxiety test. Next they were presented with nine scenes (via videotape or written scripts) in which a male or female, authority or peer, made an unreasonable request. They were then given a list of 15 possible consequences of assertiveness/nonassertiveness and were asked to rate the utility (desirability) of each. Then the scenes were presented again, and after each scene the participants assessed their subjective probabilities that each of the aforementioned consequences would eventuate should they act either in an assertive or nonassertive manner. Finally, for each scene they were asked whether they would in fact comply or refuse.¹ The utilities and subjective probabilities were used to compute a SEU for each

¹ Clearly, it is also possible to choose not to act in a conflict situation (e.g., to wait for further information), but for convenience sake we have assumed two general and mutually exclusive classes of behavior even if this is an oversimplification.

scene for each participant, and the comply-refuse statements were used to compute an overall index of BI for each participant.

Participants

Sixty-four women attending undergraduate psychology classes and 47 women in a professional dental hygiene program participated in this study. The women were asked to attend one session lasting about 1½ hours and were seen in small groups. Following the experiment they were either given credit or were offered a short assertiveness training course.

Procedure

Participants were told that this study concerned decision making in difficult interpersonal situations; the term *assertiveness* was not mentioned until the debriefing explanation following the experiment. First they were given the Rathus Assertion Inventory (Rathus, 1973) and the Trait scale of the State-Trait Anxiety Inventory (Spielberger, Gorsuch, & Lushene, 1970). They were given a list of 15 positive and negative consequences (feelings and actions) that might result from interpersonal conflict. This list was developed by presenting six assertiveness trainers with three sample situations and asking them to generate lists of positive and negative consequences commonly experienced by clients. The resulting core list of consequences was similar to those suggested by Alberti and Emmons (1970).

Participants reviewed the nine video or written scenes rapidly to give them an idea about what they were like and then rated their utilities for the consequences. They were asked first to decide if the consequence was positive or negative and then to show how positive by marking one end of a scale that ran from 1 to 4, or if negative, how negative by marking the other end of the scale from -4 to -1. A response of 0 indicated that the consequence was neutral.

They then were given a booklet of nine identical response sheets. The sheets were divided into two sections, the first for compliance and the second for refusal. Each was followed by a list of 10 consequences, which were generated from the core list used for the utility ratings. They were told that for each scene individually, they were to mark on a scale from 1 to 100 how probable each consequence would be if they personally were to comply and then how probable each would be if they personally refused to comply. (This method has been used successfully by Holmstrom & Beach, 1973; and Muchensky & Fitch, 1975.) When the probabilities were completed, participants were asked to mark whether they thought that they *actually* would comply or refuse the request; the proportion of refusals over the scenes was taken as the overall BI measure for each person.

The Scenes

Eight of the nine scenes that were used were from among those developed by Nedelman (1977) for a

study of the generalization of assertive behaviors; all eight scenes involved an unreasonable request. A ninth scene, involving a reasonable request, was included to see if there was a tendency for subjects to refuse to comply regardless of the appropriateness of the request; results for this scene revealed no such bias and responses to it are not included in the data analysis. The scenes and characters were described by a female narrator. Then there followed a direct request by the antagonist to the participant. Antagonists were either males or females, presented as either authorities or peers; each participant saw two examples of the four male-female/authority-peer combinations. For each session the sequences of scenes were presented in a scrambled order, with the restriction that each scene was presented as the first one in one of the sessions to spread the effect of presentation order.

Half of the participants saw videotape dramatizations of the scenes, and half received the same scenes as written scripts in booklet form.

Analysis of SEU

An SEU was computed for each scene by multiplying rated utilities by the rated probabilities of each of the 20 consequences. The SEUs were computed separately for compliance and for refusal and were then combined to yield a single score for each scene by subtracting the smaller SEU from the larger and assigning a minus sign to the difference if the larger SEU was for compliance and a plus sign if it was for refusal to comply. This was done so that there would be only one SEU datum for each scene rather than two. (Two would be awkward to analyze.) SEUs for each pair of similar scenes were averaged giving each participant four SEUs, one for each of the variations—male authority, female authority, male peer, and female peer. First, participants were divided into three equal-sized groups according to their scores on the assertion measure (high, medium, and low). An analysis of variance for repeated measures was performed to compare groups' SEUs and to examine the effects of the sex and status of the antagonist on SEUs. Then the analysis was repeated dividing the participants into three equal-sized groups according to their scores on the anxiety measure (high, medium, and low). Finally, participants were again divided into three equal-sized groups on the basis of BI (high, medium, and low), and the analysis was repeated. Significant interactions were further analyzed using Duncan's multiple-range test, and only significant effects will be discussed.

Results

Assertiveness and Anxiety

The first analyses were to see whether measured assertiveness and/or measured anxiety were related to BI and to each other. Table 1 contains the intercorrelations among these three variables for the psychology

students and the dental hygiene students separately. (Later analyses show the two groups to be significantly different.) Neither the assertiveness nor the anxiety test scores were significantly related to BI, and they were only slightly negatively related to each other.²

The SEUs

As was previously explained each participant's SEU was computed for each of the four different kinds of scenes. Because these SEUs are situation specific, it is inappropriate to combine them; thus there was no single overall SEU for each of the participants that could be correlated with their single BI measures. Therefore, participants were divided into psychology and dental hygiene students, and each group of students was divided into three equal-sized groups on the basis of the BI measure: high, medium, and low. Then a $3 \times 2 \times 2 \times 2 \times 2$ repeated measures analysis of variance was performed on the SEUs, with the independent variables of BI (high, medium, and low refusal to comply), kind of student (psychology or dental hygiene), method of presentation of the scenes (video or written), and the variables that defined the scenes; the status of the antagonist (authority/peer); and sex (male/female). Similar analyses were performed using the assertiveness test scores and the anxiety test scores instead of BI, both analyses showed these two variables to be unrelated to the SEUs, so they will not be discussed further.

Table 1
Multiple Correlations Among the Assertiveness Test Scores, the Anxiety Test Scores, and Behavioral Intent (BI) for Two Kinds of Students

Group	R
Psychology students	
Assert and anxiety	-.25*
Assert and BI	.18
Anxiety and BI	.03
Dental hygiene students	
Assert and anxiety	-.28*
Assert and BI	.26*
Anxiety and BI	-.17

Table 2

Interaction Effects of Behavioral Intent (BI), Method of Presentation, Sex and Status of Antagonist Mean Subjective Expected Utilities

Variable	Status		Sex	
	Authority	Peer	Male	Female
BI				
High	11.44	10.54		
Medium	11.23	7.96		
Low	6.21	1.97		
Presentation				
Video			6.80	5.24
Written			10.61	7.57
Sex				
Male	11.15	6.83		
Female	7.28	5.87		

Note. For Method of Presentation \times Sex of Antagonist, $F(1, 94) = 4.1$, $p < .05$. For Sex \times Status of Antagonist, $F(1, 94) = 6.6$, $p < .01$. For BI \times Status of Antagonist, $F(2, 94) = 5.7$, $p < .01$.

For the BI analysis all main effects and three interactions (BI \times Status, Method of Presentation \times Sex of the Antagonist, and Status \times Sex of the Antagonist) were significant.

The first main effect is BI, $F(2, 94) = 9.6$, $p < .01$, with a mean SEU for the high BI group of 10.99, for the medium BI group of 9.60, and for the low BI group of 4.09. Using Duncan's test the difference between the means of the high and low BI group was significant at $p < .05$. The medium BI group did not differ from either the low or high BI groups.

For the second main effect, kind of student, $F(1, 94) = 6.8$, $p < .05$, the psychology students has a group mean SEU of 6.67 and the dental hygienists' mean was 9.42. This shows that the SEUs for the latter favored refusal more than did the SEUs for the psychology students. Further, the mean BI for the hygienists (1.72) was significantly

² In light of this result for the Rathus scale, readers familiar with this scale may be interested in the obtained means and standard deviations (for psychology undergraduates, $M = 12.62$, $SD = 20.49$; for dental hygiene students, $M = 10.60$, $SD = 22.41$).

higher, $t(104) = 2.80$, $p < .01$, than the mean BI for the psychology students (1.44), indicating that the hygienists said that they would refuse to comply with the requests in the scenes more often than the psychology students did.

The third main effect, method of presentation of the scene, $F(1, 94) = 10.0$, $p < .01$, had a SEU for the written presentation (9.09) that was higher than for video presentation (6.02). The corresponding mean BIs were 1.55 for the written presentation and 1.50 for video presentation, $t(104) = .5$, *ns*. These results suggest that BI is independent of the method of presentation but that the participants' expectations for refusal (SEU) were more positive for those who saw the written scripts, and that those who saw the videotapes—a more realistic stimulus—were more likely to have less favorable expectations for refusal.

The fourth and fifth main effects were for the status of the antagonist, $F(1, 94) = 27.3$, $p < .01$, with mean SEUs of 9.22 for authorities and 6.35 for peers and for the sex of the antagonist, $F(1, 94) = 45.6$, $p < .01$, with mean SEUs of 8.99 for males and 6.58 for females. Participants' expectations for assertion to peers and to women were more negative than for assertion to authorities and males. Because these two variables define the scenes rather than divide participants into groups, as did the student and presentation variables, BIs could not be calculated for each of the four variants for comparison with the SEUs. However, it is possible to calculate the proportion of times that the participants stated an intent to refuse to comply for each level of the two variables. For authorities the proportion of refusal was .85, for peers it was .69, for males it was .77, and for females it was .76. Because these proportions each involve multiple contributions by all of the participants, no statistical tests can be performed. However, the proportions appear to be congruent with the SEU for status and less so for sex.

All three significant two-way interactions involved the status and sex variables. These are shown in Table 2.

Within the different kinds of scenes, the participants in the high and the low BI

groups differed significantly in their SEUs for refusal to comply in scenes, although this is not true of their response to the scenes involving authority figures. For both scene types, as one moves from high to low BI, the SEUs for refusal to comply to authority and peer demands become increasingly disparate, though these differences did not reach statistical significance. For those persons who have a high BI to refuse, the difference between refusal to peer and to authority was only .90; for the medium group it was 3.27, and for the low group it was 4.24. For the participants with a low BI to refuse, unlike the high group, it appears much more difficult to refuse requests made by peers than by authorities.

The interaction between method of presentation and sex of antagonist shows that the SEUs for written presentation were higher overall than the SEUs for the video presentation for both scene types. SEUs for refusal to comply with males were higher than SEUs for refusal to comply with females for both methods of presentation.

The interaction between sex and status of the antagonists shows that the SEUs for refusal were higher for male authorities than for female authorities, male peers, and female peers. The SEUs for female authorities were higher than for female peers, with no differences between the remaining categories. The corresponding proportions of refusal to comply statements (BI) for the four kinds of antagonists are .88 for male authorities, .82 for female authorities, .67 for male peers, and .71 for female peers—moderate agreement with the SEUs. In sum, it appears that the highest SEUs for refusal occurred among the dental hygiene students, for participants with high BI, and when participants are confronted with authority figures, particularly males.

Utility and Probability

Because SEU is clearly related to BI, it is appropriate to see if the differences between participants who frequently state that they intend to refuse to comply and those who less frequently state intention to refuse can be attributed to differences in either their utilities for the possible outcomes or their subjective probabilities that these outcomes

will occur. To do this the participants were divided into groups on the basis of the kind of student (psychology, dental hygiene), method of presentation (video, written), and BI (high, low). A repeated measures analysis of variance using utilities as the dependent variable yield no significant effects of any of the independent variables. As can be seen in Figure 1, students at both levels of BI evaluated the utilities in the same way.

A similar analysis was performed using the probabilities as the dependent variable. Here all three variables (type of student, method of presentation, and BI) had a significant effect on the probability estimates, and all interactions also were significant. This is illustrated for high and low BI participants in Figure 2.

The graph shows that if they were to comply, the low BI participants would expect the positive consequences to be more probable, $t(62) = 6.08, p < .01$ than would the high BI participants. Similarly, if they were to refuse to comply, the low BI participants would see the positive consequences as less probable, $t(62) = 8.33, p < .01$, and the negative consequences as more probable, $t(62) = 4.29, p < .01$, than the high BI participants. In short, the difference between high and low BI participants is not in their utilities for the positive and negative consequences but in their different perceptions of the probabilities of those positive and negative consequences occurring should they elect to comply or to refuse to comply.

Discussion

Schools and Presentations

Initial analyses revealed significant effects for the type of students and for the method of presentation of material. SEUs for the dental hygiene group were uniformly higher than SEUs for the psychology students. Attitudes of the former toward the requests in the scenes as suggested by their higher intent to refuse may have been mediated by their expectation that they would soon be employed in a highly authority-oriented profession. The experience and advice of those few who had already worked as dental assistants contributed to this concern.

Figure 1. Utilities for participants who were high and low in behavioral intent.

The effect of presentation was also significant. SEUs for the written scenes were higher for both sex and status and across schools, although the pattern of refusal to scenes did not differ. Even though the written scenes allowed participants to make greater use of their own experience in evaluating the scenes, the demand of the antagonist was less immediate. Participants evaluated the consequences for refusal as more negative when the request was made via videotape. Videotape has been a successful adjunct to treatment in assertive training studies for modeling appropriate responses (Hersen, Eisler, Alford, & Pinkston, 1973), and for assessing change (Hersen, Eisler, & Miller, 1973). Although it has not been systematically tested in the literature, it is likely to be a better medium than audiotape or written instructions, since the stimulus it presents apparently is experienced as "more real."

The Scenes

Although many studies acknowledge the variation of task difficulty involved in assertion, no systematic investigation of the subject's evaluation of the risks involved exists in the literature. Typically authors deal with this issue by hierarchically ordering materials differing in risk or task difficulty (Alberti & Emmons, 1970; Piaget & Lazarus, 1969; Wolpe & Lazarus, 1966). Situations involving interactions with persons of the same sex, peers, or persons who have a distant relationship are presented prior to those involving persons

Figure 2. Probabilities for participants who were high and low in behavioral intent.

of the opposite sex, spouse, or an authority figure (McFall & Lillisand, 1971). The rationale for this is to provide success in situations involving less risk of failure and emotional concomitants and to desensitize the anxious patient to difficult interactions. This pattern has become institutionalized, but, as was demonstrated in this study, it may not reflect the order of task difficulty for all participants. Perhaps since all subjects were students and were less likely to be confronted with authority figures in the work place, it is possible that they feared the consequences of assertion to authorities less than they feared "negative" consequences in relationships with peers. If this is the case, a training program designed to teach assertion should take into account the participants' own evaluation of the salient perceived risks involved in the new behavior and the current situation. It is likely that these may differ from participant to participant and from established training procedures.

Behavioral Intent

The measure of intent to refuse (BI) was highly related to SEU for the content scenes. This attests to the situational specificity of assertion. It suggests that assertiveness is not a trait that applies equally across situations varying in sex and status of the antagonist and presumably varying also in the amount of risk entailed.

In this study BI is not to be taken as an actual indication of the participant's willingness to assert in a real-life situation. However,

a number of studies have found a high correlation between behavioral intent and actual behavior in a variety of situations (reviewed in Fishbein & Ajzen, 1975). These authors assert that intent is the best indication of actual behavior, but they qualify its ability to predict behaviors in situations in which there is a time interval between the intent and the behavior, and when the behavior in question depends on the actions of others. Additionally, when the stimuli are highly artificial, as in this experiment, intent may be no more than an indication of the subjects' desire to behave in the intended manner.

The fact that there were no systematic differences in SEU for participants scoring high and low on the personality measures may have been a function of the tests used, and they may also reflect the inadequacy of assigning a "trait" value to a situation-specific task. A major issue in the literature has been the specificity of the assertiveness response and the expectations that can be made for generalization. Hersen, Eisler, and Miller (1973) and Wolpe and Lazarus (1966) argued that assertion is specific to the social context in which it occurs. Others have found some degree of transfer of training as a result of their intervention (McFall & Lillisand, 1971; McFall & Marston, 1970; Nedelman, 1977).

Utility and Probability Components

Participants high and low in BI to refuse unreasonable requests did not differ in the way they valued the utilities of the consequences. However, participants differed significantly in their perception of the probabilities of the consequences occurring as a result of their behavior. For refusal, these trends were reversed; participants with high BI for refusal saw the positive consequences of refusal as more likely to occur and the negative consequences as less probable. For both events the probability endorsements of low BI participants were generally more constricted, whereas high BI subjects gave more extreme probabilities.

This result is consistent with results reported by Mitchell and Knudsen (1973), who separated out the effects of utilities and probabilities.

ities. Comparing college students and business students, they found that although the students did not differ in their valuation of occupational goals, they held significantly different probabilities that a career in business would allow them to attain those goals.

Findings support the hypotheses that intent to refuse to comply with an unreasonable request depends on the attributes of the situation. Additionally, subjects did not differ in their valuation of the positive and negative consequences, but instead they differed in their expectations that a particular consequence would occur should they elect to refuse to comply with unreasonable demands.

Issues for Training

Research on assertiveness has had its greatest impact on applied methods for clients. Past studies (Hersen, Eisler, & Miller, 1973; McFall & Marston, 1970) have identified behavioral components of assertiveness that can be taught to nonassertive persons and used in a variety of situations. In the present study it appears that participants scoring on all levels of an assertion inventory also respond to situations differentially according to the sex and status of the antagonist and presumably according to the degree of risk that they perceive to be a consequence of their behavior.

In designing a comprehensive assertiveness training program, these results suggest that the focus of training should be on changing the participant's cognitive expectations about the results of his or her behavior, as well as on changing attitudes or specific behaviors. This approach assumes that the average client has greater knowledge about appropriate interpersonal behaviors than might be found among the hospitalized schizophrenic male patients in the Hersen et al. studies. In fact, the thrust of training has not been directed toward this latter group but rather toward women and college students who may have adequate skills but who do not act assertively when they perhaps should. The Gottman and Schwartz study (Note 1) suggests that both assertive and nonassertive people know the appropriate behaviors. It may be that the primary "skill deficit" lacking in nonassertive

persons is their inability to accurately estimate the consequences of their assertion. If this is true, greater emphasis must be placed on changing the person's cognitive expectation of the consequences. This may involve a process of teaching the client a new set of expectancies about possible outcomes based on the characteristics of differing situations. Since information affects beliefs about consequences, active participation such as role playing is likely to be an effective strategy for change, because it exposes the person to new information and allows for change in belief. Additionally, as suggested by Mitchell and Biglan (1971), exploring the components of the client's expectancies in therapy might change the client's perception of instrumental relations between behavior and outcomes or the evaluations of the probabilities of outcomes occurring.

This research also suggests that training programs might profit from a broader appreciation of the client's negative as well as positive evaluations of the consequences of assertion. The weighting of these consequences appears to differ from situation to situation and may determine the persons' willingness to respond. Assertive behavior may be realistically evaluated by the subject as counterindicated in a given situation. For example, in some situations compliance to a mildly unreasonable request may have the secondary positive consequences of strengthening a friendship. In other situations the effect might be to advance a long-range goal. It may be necessary, as Hersen, Eisler, and Miller (1973) suggested, to train for generalization of assertive behavior, in this case to teach clients appropriate expectations in a variety of situations. It may also be important to teach relevant others to change their expectations as the client changes his or hers. Since we have only treated one type of assertion in this study, refusal to comply with an unreasonable request, further investigation is needed to see whether other assertive responses (complimenting, standing up for one's opinions, etc.) are similarly affected by the situational variables and by the participant's expectations of the consequences.

A number of issues have been raised in this study that have not been dealt with in the

literature of assertion and that seem worthy of further investigation. These include an appreciation of the client's perception of the risk involved. The traditional pattern of training female peer situations first because they involve less risk than authority situations does not take into account the possible ascendance of peer and friendship values in a female college population. In an analogue study of this type, the use of self-report and self-ratings are limited in their ability to predict actual behavior. It appears, however, that the decision/expectancy model has value as a research tool in specifying under what conditions a participant might choose to act in an assertive manner in a given situation. Future research might investigate the ability of this approach to predict and shape the responses of individuals in real-life situations.

Use of Paradoxical Intention in a Behavioral Program for Sleep Onset Insomnia

L. Michael Ascher and Jay S. Efran
Temple University

Sleep onset insomnia seems often to be based on performance anxiety associated with a client's fears of being able to fall asleep; in some cases, a therapeutic program might actually exacerbate this performance anxiety by focusing on the client's efforts to voluntarily control the sleep onset process. Five cases of sleep onset difficulty, unusually resistant to a conventional behavioral program for this problem (i.e., deep muscle relaxation and systematic desensitization), were exposed to paradoxical intention suggestions requiring that they try to remain awake as long as possible, rather than attempt to fall asleep. A rapid reduction of sleep onset latency occurred following the shift from the conventional program to the paradoxical intention instructions.

Frankl (1975) has recently provided a more detailed and updated description of "paradoxical intention," a psychotherapy technique that he developed in the framework of logotherapy. He has also begun to articulate some of the links between this technique and behavior therapy approaches. This article reports the use of paradoxical intention as a complement to other behavioral procedures in cases of sleep onset "insomnia" that proved resistant to treatment.

Deep muscle relaxation as developed by Jacobson (1938) and modified by Wolpe (1958, 1974) has been used with success in sleep disturbances due to other than physiological factors (Kahn, Baker, & Weiss, 1968; Nicassio, & Bootzin, 1974). There are, however, a significant number of clients with whom relaxation alone is not sufficient to produce the desired degree of improvement. In such cases, behavior therapists have commonly used systematic desensitization focused either on the anxiety-provoking themes that occupy the client prior to sleep onset or toward anxiety directly related to the sleep situation (Borkovec, Steinmark, & Niu, 1973; Geer & Katkin, 1966). Other behavioral methods, such

as covert conditioning, thought stopping, and operant stimulus control have also been used singly and in combination.

The present article explores the use of paradoxical intention as an ancillary treatment with individuals for whom the relaxation-desensitization program seemed insufficient. It is relatively easy to apply and usually produces immediate behavior changes without the complications of medication (Kales, Allen, Schaff, & Kales, 1970). Briefly, paradoxical intention can be viewed as a behavioral prescription requiring clients to perform responses that appear to be incompatible with the goal for which they are seeking therapeutic assistance. Thus, in the present context, clients with sleep onset disturbance are requested to try to *remain awake* for as long as possible, rather than to focus on trying to fall asleep. In other words, they are asked to exaggerate the very behavior that they would like to reduce. In the present study, the course of treatment of five clients illustrates the use of paradoxical intention within a behavioral framework when the sleep difficulty did not yield to a conventional relaxation-desensitization program.

Method

Subjects

All five clients had applied for treatment to the clinic of the Behavior Therapy Unit of the Department of

Requests for reprints should be sent to L. Michael Ascher, Behavior Therapy Unit, Eastern Pennsylvania Psychiatric Institute, 3300 Henry Avenue, Philadelphia Pennsylvania 19129.

Table 1
Characteristics of the Five Clients

Client	Sex	Age	Marital status	Occupation	Average sleep onset latency (minutes)	Length of complaint (years)	Primary presenting problem
A	Male	32	Single	Lawyer	60	5	Primary erectile dysfunction
B	Male	27	Married	Graduate student (mathematics)	45	12	Interpersonal difficulties
C	Female	41	Married	Housewife	90	21	Sleep onset
D	Female	23	Married	Social worker	45	3	Sleep onset
E	Male	25	Single	Salesman	75	4	Sleep onset

Psychiatry at Temple University. The first author served as the therapist and conducted weekly sessions individually with each client. The clients are further described in Table 1.

Procedure

Two weeks prior to initiating therapy directed at sleep onset difficulty, each client was asked to chart the approximate length of sleep onset latency each morning in addition to recording other details relevant to the sleep situation (e.g., mood when retiring, time of retiring, number of awakenings, "restfulness" of sleep).¹ Beginning with the initial session following this 2-week baseline period, and continuing for 10 weeks, all clients were instructed in deep muscle relaxation (Wolpe, 1974) with particular emphasis on the use of these exercises prior to retiring. Clients were also advised on the modification of their sleeping arrangements to produce optimal conditions for rapid sleep onset. With successive sessions, additional techniques were introduced as required (e.g., desensitization and covert conditioning). (Although the behavioral program outlined above has been of demonstrated efficacy with sleep onset difficulty, it failed to produce the desired improvement in the five cases reported in the present study. This represents about 10%-15% of individuals seen for sleep disturbance problems over a 4-year period.)

During the first session following the 10-week period, the therapist suggested that a modification in the procedure might enhance the patient's progress. Paradoxical intention was administered by instructing the client (with an appropriate rationale) *to try to remain awake*. Three clients (A, B, and E) were told that although the present program would eventually prove to be successful for them, specific details would be required to "further tailor therapy to meet their individual needs." These clients were told that the failure of the program at this point was possibly due to the lack of sufficient information regarding the sleep situation. It was suggested that since detailed descriptions of thoughts experienced just before sleep were required, they should try to remain awake as long as possible to experience these thoughts. If they fell asleep too soon, the necessary information would be unobtainable.

With the remaining two clients (C and D), it was

suggested that the relaxation component of the behavioral program was not of sufficient duration to "produce the level of relaxation requisite for sleep." Therefore, instructions were given to lengthen the number of steps (and, consequently, the length of time) required to complete the relaxation practice. Clients were advised to go through the entire procedure several times to achieve a satisfactory level of relaxation. They were asked to do this even if it meant resisting the urge to sleep.

The paradoxical intention procedure was continued for all five clients for 2 weeks. During the sessions the clients were asked how they had progressed with respect to the assigned tasks (either obtaining the thoughts experienced prior to sleep or increasing the relaxation procedure to achieve a "deeper" level of relaxation). Typically, they reported that they had not been able to accomplish the goal because they had fallen asleep too quickly. The therapist briefly expressed interest and encouragement on hearing this information but suggested that they redouble efforts to accomplish the goal, trying harder to remain awake. This entire interaction took only a short time during the initial portion of the three relevant therapy sessions, the remainder of which were devoted to continuation of the regular desensitization procedures.

Following the 2-week paradoxical intention period, four of the clients (A-D) were given no further sleep onset treatment. However, Client E was instructed to return to his previous program, which incorporated techniques focused on the reduction of anxiety-provoking thoughts experienced during the sleep onset latency period (i.e., thought stopping, covert positive reinforcement, systematic desensitization). The client remained on this program for 3 additional weeks, after which he was told that his efforts to reduce discomforting thoughts seemed to have been effective and that he should reemphasize the relaxation (paradoxical) component of the program. In this way, paradoxical intention instructions were again administered (this time

¹ These other measures seemed less relevant in this context than the latency measure, and, for the sake of brevity, they have been omitted. All of the measures followed the same pattern.

Table 2
Mean Number of Minutes to Sleep Onset for Each Week of the Treatment Program

Mean Number of Minutes to Sleep Onset for Each Patient																				
Week	Phase 1			Phase 2						Phase 3			Phase 4			Phase 5				
	1	2	M	1	2	3	4	5	6	7	8	9	10	M	1	2	M	1	2	M

SD	21.4	25.3		12.4	18.1	16.5	13	19.3	17.2	19.7	15.2	13.4	15.9		4.7	3.5				

Note. Phase 1 = baseline; Phase 2 = conventional program; Phase 3 = paradoxical intention; Phase 4 = readministration of conventional program; Phase 5 = readministration of paradoxical intention.

Results

Table 2 presents the mean self-report estimations of sleep onset latency (i.e., the duration between "lights out" and sleep onset) for each client during the 2-week baseline period (Stage 1), the 10-week behavioral program administration (Stage 2), and the 3-week paradoxical intention period (Stage 3), which represented the terminal stage for four clients (A-D). In addition, data are reported for Client E's second behavioral administration (Stage 4) and return to paradoxical intention (Stage 5). A comparison of the sleep onset latencies during the baseline period with the data following 10 weeks of behavior modification indicates that in most cases "some improvement" was obtained, even though it was judged insufficient by the client.³

The data show a marked reduction in sleep onset latency following the administration of paradoxical intention instructions to "try to remain awake." In the case of Client E, the data for the first three stages of the study are congruent with those for the remaining clients. Sleep onset latency was somewhat reduced as a result of relaxation training and behavioral procedures directed at distracting anxiety-provoking thoughts. However, presentation of paradoxical intention instructions produced a marked reduction in sleep onset latency. Reinstitution of the previous behavioral program was coincident with an increase in sleep onset latency, which decreased again when paradoxical intention instructions were readministered. Informal long-term follow-up (by telephone) indicated that each of the clients remained satisfied with their sleep behavior after a period of 1 year.

² The clients appeared to believe the treatment rationales that they were offered, although formal data on this issue could obviously not be collected in this clinical setting.

³ Formal statistical treatment is perhaps unwarranted in this study. However, the reader may wish to note that *t* tests between the baseline and behavior therapy, the baseline and paradoxical intention, and behavior therapy and paradoxical intention were, respectively, .978 (*ns*), 3.86 ($p < .02$), and 4.58 ($p < .02$).

Discussion

The present study illustrates the utility of paradoxical intention within the context of the behavioral treatment of sleep onset difficulties. A reasonable question would seem to be, why did paradoxical intention produce a change that the conventional treatment alone could not? Paradoxical intention has been shown to be effective with a wide variety of psychosomatic dysfunctions, that is, physiological processes, having autonomic nervous system innervation, which can be inhibited by anxiety. Such dysfunctions can occur, for example, with various aspects of sexual activity, elimination, and, as in the present case, components of sleep behavior.

Most people experience occasional difficulty in falling asleep. This difficulty is usually seen by the individual as an isolated event precipitated by unusual excitement or tension during the day, too much sleep prior to bedtime, and so forth. Succeeding evenings normally result in a rapid return of the individual's typical sleep pattern. However, a small percentage of people view instances of sleep onset difficulty as indicants of a trend toward decreasing levels of satisfactory functioning. This latter group considers each successive evening a test of their ability to fall asleep. The level of performance anxiety increases as each test approaches. Anxiety is assumed to have a reciprocally inhibiting relationship with sleep onset (as with sexual arousal); that is, it stimulates the sympathetic nervous system, a system that alerts the organism and is the reciprocal of the parasympathetic system, which has recuperative functions compatible with sleep onset.

Some people who experience performance anxiety at bedtime appear to focus on at least two major themes: First, they monitor their level of sleep readiness. Second, they focus on negative outcomes associated with sleep loss (e.g., difficulties that they may experience on the following day, physical well-being, etc.). For these individuals, concern about successful performance and contingencies of failure serve to increase anxiety prior to bedtime and main-

tain a high level of anxiety in the sleep situation. "Trying hard" to get to sleep only makes this cycle more pernicious.

The cycle can apparently be broken by paradoxical intention, which decreases performance anxiety by redefining the situation. The paradoxical suggestion is incompatible with the "common sense" effort that the individual has been making to perform the target response. Thus, because the conventional program was aimed at helping these individuals fall asleep more rapidly, it inadvertently supports the cycle of "performance anxiety—failure to perform—increased performance anxiety." Paradoxical intention removes the client from this system. In this article, paradoxical intention was used with difficult cases. It remains to be seen whether it would be as useful with the wider range of clients complaining of sleep onset latency.

A Scoring Manual for Literalness in Proverb Interpretation

Chris A. Hertler, Loren J. Chapman, and Jean P. Chapman
University of Wisconsin—Madison

A scoring system is offered for literalness of proverb interpretation as an alternative to scoring concreteness. For a group of 115 schizophrenic and normal subjects, literalness and Gorham's concreteness were equivalent on coefficient alpha (.85 for literalness and .84 for concreteness). Interrater reliability was .90 for both scoring systems. Nevertheless, abstraction correlated lower ($p < .01$) with literalness than with concreteness. For 77 schizophrenics, Verbal IQ correlated significantly with concreteness ($r = -.52$, $p < .01$) but not with literalness ($r = -.15$, *ns*). Thus, literalness is less affected by intelligence and by ability to respond abstractly than is Gorham's concreteness.

When schizophrenics are asked to interpret proverbs, they often respond to the proverb as a literal statement rather than as a bearer of a figurative meaning. For example, when asked to interpret the statement "When the cat's away, the mice will play," even educated and intelligent schizophrenic patients may explain the actions of cats and of mice, rather than of people. This article offers a system for scoring literalness of proverb interpretation.

Dozens of writers have discussed literalness of proverb interpretation, but scoring systems treat it as a manifestation of concreteness. The scoring systems score either concreteness or abstraction, which is merely a term for accuracy of proverb interpretation that is incompatible with literalness. Both low abstraction and high concreteness are usually viewed as implying literalness. However, scoring for either concreteness or abstraction classifies literalness with various other kinds of poor performance that have little to do with literalness. Literalness is a more specific error than either

concreteness or lack of abstraction. Literalness is an active attempt to interpret the words of the proverb as a literal message rather than as symbols to be interpreted.

The most commonly used scoring system for proverbs is that of Gorham (1956a, 1956b), who scores abstraction and concreteness separately. He offered a detailed scoring system for abstraction but evidently regarded concrete responses as so obvious that no formal scoring system need be offered. Gorham (1956a) stated his criteria for concreteness very briefly.

Concrete answers are usually apparent to a clinical observer. They stick closely to the symbols of the proverb. In schizophrenics, it is common for patients to substitute "That's right," "exactly," "that is not so because," or "yes" and "no" for a restatement of the proverb in concrete form. These answers are considered to be concrete." (p. 3)

Gorham supplemented this statement with one example of a concrete response to each of seven proverbs.

Many responses by both normal subjects with low intelligence and schizophrenics stick closely to the symbols of the proverb but yet are not literal interpretations of the proverb. If a subject is unable to interpret the proverb but is verbose, he or she will talk about the symbols. Subjects who cannot interpret a proverb appropriately often simply repeat some of the words of the proverb without further elaboration, give associate responses to the words,

relate the words to their own experience, or talk in other discursive ways about the proverb that they are asked to interpret. Such talk is not evidence that he or she interprets the symbols literally, but it would be scored as "concrete" by Gorham's criteria. For example, one schizophrenic responded to "The worst spoke in the wheel breaks first" with "Wheel breaks, brake locks, break off." Another patient responded to "He who stumbles twice over one stone deserves to break his shins" with "I don't stumble, walk straight, never stumble, got to control me, can't see." Both of these responses stick closely to the words of the proverb and, hence, would be scored as concrete, but they are not attempts at a statement of a literal meaning. Gorham's concreteness seems to reflect in large part dullness and a lack of accuracy. In schizophrenia, concreteness is heavily affected by a failure to focus on the task of interpretation and by other aspects of generalized deficit. Literalness should be less affected by generalized deficit because it is a more specific kind of error. Because literalness is less a reflection of generalized deficit than is concreteness, a score for literalness should depend less than does concreteness on both Verbal IQ and abstraction.

The system of scoring literalness that we offer here labels all appropriate answers as nonliteral and only some incorrect answers as literal. This system provides for scoring each proverb on a 3-point scale. This follows from dividing the proverb into two halves, each of which could receive a literalness score of 0 or 1. Thus the total literalness score for the sum of the two halves could be 0, 1, or 2. For example, the proverb "Rome was not built in a day" is sometimes interpreted as "Rome took a long time to build." In this response, *Rome* is treated literally, and *in a day* is treated abstractly, which yields a total literalness score of 1.

The scoring principles offered here could be applied to the interpretation of any figurative statement, although we developed them for proverbs from Gorham's (1956a, 1956b) clinical form of the Proverbs Test. Actually, not all 36 of Gorham's items are proverbs in the sense of being figurative statements to be interpreted. Some items are, instead, aphorisms that should be interpreted literally. Examples

are "The more cost, the more honor" and "Where there's a will, there's a way." We do not include such items in our scoring system. We regard 24 of Gorham's items as clearly figurative statements and, therefore, include them. These are Form I, Items 2-9 and Item 12; Form II, Items 1-7 and Item 10; Form III, Items 1, 2, 5, 6, 7, 9, and 11.

Following the example of Friedes, Grisell, Levin, Dobie, and Cohen (Note 1), we designate certain of the words in each half of the proverb as symbols that must be generalized or interpreted to obtain a correct abstract interpretation. For example, in the proverb, "A drowning man will clutch at a straw," *drowning* and *straw* are symbols that must be interpreted, but *clutch* is not. If *drowning* or *straw* are repeated in the answer, a score for literalness must be considered. However, the appearance of *man* or *clutch* in the answer need not imply literalness. For example, the response "A man who is in trouble will clutch at any method to save himself" is an adequate abstract interpretation rather than a literal one.

Scoring Principles for Literalness

For the sake of brevity, we will illustrate each scoring principle with responses to the proverb "Rome was not built in a day." The two halves of this proverb are *Rome* and *was not built in a day*. The symbols to be generalized in an abstract response are *Rome*, *built*, and *day*.

An entire proverb is considered completely unscorable for literalness if the entire response consists of any of the following:

1. An "I don't know," without further elaboration.
2. A reference to a personal experience of the subject as a substitute for interpreting the proverb, for example, "I have never been to Rome."
3. A response that has no recognizable relationship either to the literal meaning of the proverb or to a possible interpretation of the proverb. Responses can be judged as falling in this category even if they contain one or more of the symbols of the proverb, for example, "Rome is in Italy."
4. A repetition of the proverb without further elaboration, for example, "Rome was not built in a day."

5. A repetition of only part of the proverb without further elaboration, for example, "Built in a day."

6. A semantic associate or a clang associate to one of the symbols without further elaboration, for example, "Paris," or "Cathedral domes."

7. Any single word other than yes or no and other than an equivalent to yes or no such as absolutely. An example of the unscorable response is *Italy*.

8. A bizarre or autistic response, with or without further elaboration, for example, "Roman vices accentuate carnal lust" or "Roman vices can't be learned quickly."

9. No response whatever.

Note, however, that many of these kinds of responses are scored if the subject adds other words in the response. See examples below.

A proverb receives a total literalness score of 2 if

1. The response is a reason for the verity of the proverb as literally stated or is an elaboration of its meaning and the explanation or elaboration is based on either physical attributes of the symbols or associates to the symbols in the proverb, for example, "Rome is a big city."

2. The response is yes or no or an equivalent response.

3. Both halves of the proverb receive a literalness score of 1 by the criteria listed below.

When the response is scorable, one half is scored 1 for literalness if

1. The response half includes a repetition of a symbol or symbols from the proverb half, for example, "Rome took a long time to complete." *Rome* is a repetition of a symbol. *Took a long time to complete* is an appropriate abstract response for the proverb half. The total literalness score is 1.

2. A synonym for a symbol or a rewording of a symbol from the proverb half is included in the response, for example, "The capital of Italy took a long time." *Capital of Italy* is a synonym for the symbol *Rome*. The total literalness score is 1.

3. The response half includes physical attributes of a symbol from the proverb half, for example, "A big city can't be built in a day."

A *big city* states physical attributes of the symbol *Rome*. *Built in a day* is a repetition of a symbol. Both halves earn a literalness score of 1. The total literalness score for the proverb is 2.

4. The response half is primarily a semantic associate to a symbol from the proverb half, for example, "It took more than one day to build Paris." *Paris* is a semantic associate to *Rome*. *It took more than one day* is a rewording of *not built in a day*. The total literalness score is 2.

A scorable response meeting none of the criteria for literalness receives a literalness score of 0. Responses that are scored 0 include the following: (a) a response that is correct (abstract) according to the Gorham scoring manual; (b) another proverb that has the same meaning as the original proverb; and (c) an attempt at an abstract interpretation of the proverb, even though incorrect; for example, "Big projects require great will power."

The total literalness score for a proverb is the sum of the scores for the two halves. If one half is unscorable, the total score is the score of the scorable half.

The divisions of each proverb into halves and the designated symbols of each proverb are as follows: Form I: 2. Rome/was not built in a day. Symbols: Rome, built, day. 3. When the cat's away/the mice will play. Symbols: cat, mice. 4. Barking dogs/seldom bite. Symbols: Barking, dogs, bite. 5. A stream/cannot rise higher than its source. Symbols: stream, source. 6. Don't swap horses/when crossing a stream. Symbols: horses, stream. 7. The used key/is always bright. Symbols: key, bright. 8. Gold goes in/at any gate except heaven's. Symbols: gold, gate. 9. One swallow/doesn't make a summer. Symbols: swallow, summer. 12. Don't cast pearls/before swine. Symbols: pearls, swine. Form II: 1. He who stumbles twice over one stone/deserves to break his shins. Symbols: stumbles, stone, break, shins. 2. Don't judge a book/by its cover. Symbols: book, cover. 3. The proof of the pudding/is in the eating. Symbols: pudding, eating. 4. One may ride a free horse/to death. Symbols: ride, horse, death. 5. A rolling stone/gathers no moss. Symbols: rolling, stone, moss. 6. Strike/while the iron is hot. Symbols: strike, iron, hot. 7. All is not gold/that glitters. Symbols: gold,

Table 1

Mean Literalness, Concreteness, and Abstraction Scores on 15 Proverbs

Variable	Schizophrenics	Normal subjects
Gorham's concreteness ^a	9.68	2.10
Literalness	7.65	1.34
Gorham's abstraction	6.53	17.51

^a The concreteness values for the (0, 1) Gorham system have been doubled to make them comparable to the (0, 1, 2) values for literalness.

glitters. 10. Let sleeping dogs/lie. Symbols: sleeping, dogs, lie. Form III: 1. The sun/shines upon all alike. Symbols: sun, shines. 2. The grass is always greener/in the other fellow's yard. Symbols: grass, greener, yard. 5. A drowning man/will clutch at a straw. Symbols: drowning, straw. 6. Too many cooks/spoil the broth. Symbols: cooks, broth. 7. The worst spoke/in the wheel breaks first. Symbols: spoke, wheel. 9. It never rains/but it pours. Symbols: rains, pours. 11. There's many a slip twixt the cup/and the lip. Symbols: cup, lip.

Use of the Scoring Scheme with Clinical Groups

Forms II and III of the Gorham Proverbs Test were administered to 77 schizophrenics and 38 firefighters. A brief verbal IQ test consisting of the Comprehension, Vocabulary, and Similarities subtests of the Wechsler Adult Intelligence Scale was also given to these schizophrenics. The firefighters cannot be viewed as control subjects for the schizophrenics because of the lack of full information on their demographic characteristics. The firefighters' data do, however, provide some information on literalness scores of normal subjects.

Mean age of the schizophrenic sample was 37.3 years ($SD = 10.2$), mean years of education was 11.7 ($SD = 3.3$), and mean score on the Hollingshead Index of Social Position was 47.2 ($SD = 15.2$). Mean prorated verbal IQ on the brief intelligence test was 92.5 ($SD = 18.0$). Sixty-two percent of the sample was male, 38% was female. Ninety-five percent was white, 5% was black. Mean score on the Phillips Scale of Premorbid Adjustment was

17.7 ($SD = 4.4$). Mean length of hospitalization was 109.6 months ($SD = 109.9$).

All firefighters were white males. Assuming that the average firefighter receives a high school diploma, their average score on the Hollingshead index would be 51.0. No information on the age, IQ, or marital status of the firefighters was available.

The Proverbs Test was administered using Gorham's instructions, and the responses were scored for literalness by the first author and for concreteness using Gorham's criteria by a graduate student. The scorers were kept blind as to whether a protocol was that of a schizophrenic or a normal subject. To assess interrater reliability, a third scorer rated 40 schizophrenics' protocols according to both systems. To assess the relationship of adequacy of proverb interpretation to both concreteness and literalness, the graduate student also scored all protocols for abstraction using Gorham's manual.

Reliability

The coefficient alpha estimate of reliability for the 115 subjects was .85 for literalness, .84 for Gorham's concreteness, and .92 for Gorham's abstraction. The corresponding values for the 77 schizophrenics were .82 for literalness, .81 for Gorham's concreteness, and .92 for Gorham's abstraction. The correlation between concreteness and literalness was .80 for both groups combined and .74 for the schizophrenics. Interrater reliability for the 40 subjects was .90 for both concreteness and literalness.

Relation to Clinical Status

Table 1 gives the mean scores of both groups according to both scoring systems. As seen in Table 1, both groups received lower scores on literalness than on Gorham's concreteness. Schizophrenics were significantly different from normal subjects on literalness, concreteness, and abstraction ($p < .001$, in each case).

Relation to Intelligence and to Abstraction Score

For the schizophrenics, Verbal IQ correlated $-.52$ ($p < .01$) with concreteness but only

-.15 (ns) with literalness. Thus literalness is less affected than concreteness by sheer intellectual ability. We interpret these values to mean that literalness is less affected than concreteness by generalized deficit. The relation of score on abstraction to literalness and to concreteness lends further support to this interpretation. For the schizophrenics, abstraction correlated $-.64$ with Gorham concreteness and $-.48$ with literalness. Thus abstraction accounted for 41% of the variance of concreteness but only 23% of the variance of literalness. Both correlations were inflated by the fact that concreteness and literalness were obtained from the same responses as abstraction, but this artifact should not affect the correlation for literalness any differently than the correlation for concreteness. The difference between the two correlation coefficients was significant, $t(74) = 2.61, p < .01$, as indicated by a t test for correlations based on dependent data. For the combined group of normal and schizophrenic subjects, abstraction correlated $-.73$ with concreteness and $-.62$ with literalness. Thus abstraction accounted for 53% of the variance of concreteness and 38% of the variance of literalness. The difference between the two correlation coefficients was, again, significant, $t(112) = 2.65, p < .01$.

Conclusion

Literalness of proverb interpretation is less affected by intelligence and by ability to respond abstractly than is Gorham's concreteness. Concreteness depends too much on generalized intellectual deficit to be maximally useful for describing schizophrenic thought disorder. Literalness is an important and more specific kind of error than concreteness and is less affected than concreteness by generalized deficit. The present scoring scheme for literalness should be useful in many situations in which Gorham's concreteness has been used in the past.

Case Study

Cohesive and Dispersal Behaviors: Two Classes of Concomitant Change in Psychotherapy

This article differentiates between two important classes of behavior that can be identified in any psychotherapy. One class concerns *cohesive* behaviors (Type C), which bring organisms together, and the other concerns *dispersal* behaviors (Type D), which drive organisms apart. This study examined changes in C and D behaviors that occurred during the first 100 hours of the psychoanalytic treatment of Mrs. C, a woman whose presenting complaint was sexual frigidity. The data showed improvement in both types of behaviors. In addition, progress in Type D behavior preceded progress in Type C behavior, a relationship that had been predicted by the case formulation. Then we identified approximately 350 complaints made by the patient during the treatment, complaints of the form "I can't (do something)" and "I have to (do something)." These complaints also declined in frequency during the treatment.

Personality theorists (e.g., Horney, 1945; Murray, 1938) have sometimes classified interpersonal behaviors into three broad categories. This classification is generated by considering, first, whether the subject is (a) avoiding the other person or (b) getting involved with the other person. If the latter, the behavior can be further classified into

(b₁) behaviors expressing a positive involvement and (b₂) behaviors expressing a negative involvement. The resulting three categories can be labeled (a) *avoidance*, (b₁) *positive involvement*, and (b₂) *negative involvement*. Horney (1945) has called these three classes *moving away from*, *moving toward*, and *moving against* the other person. Murray (1938) has written of *abience*, *adience*, and *contrice* with similar meaning.

This study was supported in part by Grant MH 13914 of the National Institute of Mental Health. The authors would like to thank the many trainees and staff members of the Mt. Zion Psychiatric Clinic who generously supplied the clinical judgments and ratings.

The results reported here are conceptualized in more strictly psychoanalytic terms in Bulletin No. 2 of the Psychotherapy Research Group, Mt. Zion Hospital and Medical Center, by Joseph Weiss and Harold Sampson. A copy of this bulletin can be obtained from Harold Sampson, Department of Psychiatry, Mt. Zion Hospital and Medical Center, P. O. Box 7921, San Francisco, California 94120.

Behaviors involving other people, both positively and negatively, are frequently examined in psychotherapy. Those reflecting positive involvement occur when a person cooperates, collaborates, or concurs with another person, complies and shares thoughts and feelings and is intimate, warm, and loving. Ethologists (Mussen & Rosenzweig, 1973, chap. 28) have called these positive behaviors *cohesive* behaviors, since they bring organisms together. Since many cohesive behaviors begin with the letter *c* (cooperate, concur, comply), we shall call them Type C behaviors.

In contrast, behaviors reflecting negative involvement produce a psychological differentiation from the other person. They occur when a person

defines another person, disagrees with, distrusts, or disapproves of the other person, hates, criticizes or opposes the other person. Ethologists have called these behaviors *dispersal* behaviors, since they (assertively and aggressively) drive organisms apart. Since many dispersal behaviors begin with the letter *d* (defy, disagree, disapprove), we shall call them Type D behaviors. As ethologists have noted, C and D behaviors show a complex interplay throughout the phylogenetic scale, promoting the survival of both the individual and the species.

Frequently during psychotherapy people complain of having poor control over C and D behaviors. Either they are unable to express the behavior comfortably or they are unable to modulate the behavior. In the case described below, for example, the woman sometimes wanted to be affectionate but found herself provoking. At other times she wanted to demur but found herself yielding. Her poor control was accompanied by psychological distress.

Impulse Versus Behavior

To clarify poorly controlled behaviors, let us begin with a basic postulate of psychoanalytic (as well as other) theories, namely that an impulse¹ precedes any nonreflexive behavior. The distinction is analogous to the psycholinguist's distinction between the underlying abstract representation of a thought and the corresponding surface structure of verbal behavior; one, an inferred private event, precedes the other, an observable surface phenomenon. The impulse, an encoded representation, becomes decoded through a grammar that involves optional and obligatory rules and transformations; the defense mechanisms would thus be viewed as a subset of transformations that occur during decoding (cf. Suppes & Warren, 1975).

Just as the correspondence between the deep and the surface structure of language is not necessarily 1:1, the impulse is not necessarily isomorphic to the behavior; different relationships can exist between them. Sometimes an impulse is directly expressed in behavior, at other times the behavior is simply inhibited, and at still other times, the behavior is partly camouflaged by another behavior derived from another impulse. Thus, if a behavior were to exhibit both a C and a D component, we would assume that two different impulses, a C and a D impulse, both existed. An affectionate pinch, according to the postulate, would result from simultaneous impulses to hurt and to be close to the same person.

A psychological "problem" is experienced when

people lack control in translating impulse into behavior. For example, they might intend to express one impulse and yet find themselves expressing another coexisting impulse. That is, on the one hand, they might find themselves unable to express an intended behavior directly and complain, for example, that they cannot cooperate or cannot fight even though they want to. On the other hand, they might find themselves expressing a behavior more intensely or more compulsively than they want to, complaining that they *have* to share intimacies or *have* to defy even though they do not want to; such behaviors would have an obligatory quality.

A successful therapy should help people gain control over each kind of behavior. They should acquire the capacity to experience and express more directly both C and D behaviors. One goal of the following studies is to objectify such improvements and to examine the relationship between them.

Observation 1: Two Concomitant Changes

Method

This set of studies was based on a psychoanalytic case treated by a psychoanalyst who was not familiar with the views expressed here. Every session of the analysis was tape-recorded with the written consent of the patient. The analyst also took process notes during each hour describing the content of the hour. As the patient was talking, the analyst was writing. His notes, however, did not report any commentary or clinical inference; they only summarized the patient's talk and his own interventions.

A group of clinical psychologists and psychoanalysts met weekly to discuss the case. Drawing only on the process notes of the first 10 hours and information of the intake interview, they formulated the case and predicted a sequence of changes. The following case description summarizes the main details of the case and the group's formulation and clinical prediction.

Case description and formulation. The patient, Mrs. C, was a prim, married schoolteacher in her late 20s who came to treatment complaining of sexual frigidity, difficulty experiencing pleasurable feelings, and low self-esteem. Her father was a professional man, and her mother was a housewife. She was the second of four children

¹ The term *impulse* is meant to be neutral theoretically in the way that the term *underlying abstract representation* is neutral. Thus, for example, no energetic connotations are intended.

(an older sister, a younger sister, and a much younger brother). When the treatment began, Mrs. C had been married for less than 2 years. She considered her marriage successful, though she felt that her sexual inadequacy created a major marital problem.

Mrs. C's parents were described as controlled people, undemonstrative of any affection. The mother, who was an organized and efficient woman, ran the house well. She was also very controlling, and Mrs. C felt in danger of being "owned" by her. On the other hand, the mother was not able to defend herself very well. Once, for example, the patient hit the mother in the stomach, and the mother could not defend herself or correct the patient except by retiring to her bedroom in obvious discomfort, leaving the patient to feel guilty, helpless, and frightened. The patient thus came to feel capable of hurting other people and guilty over aggression and assertiveness. Between the ages of 5 and 8, she had recurrent nightmares of something happening to her mother.

The father was also undemonstrative and easily embarrassed by other people's display of affection. Although he was generally controlled, he sometimes lost control of his anger and had temper tantrums that revealed murderous rage; at times Mrs. C felt that he was capable of killing her. The father was also upset by crying women and became angry over masochistic displays from the patient.

In the period before the analysis began, Mrs. C was feeling beleaguered and upset. In situations that called for intimacy, she experienced intense ambivalence, which left her feeling confused and in turmoil. The ambivalence resulted from numerous opposing tendencies: If she had an impulse to be sadistic, for example, she felt potentially guilty. Then, identifying with her mother, she would turn to masochistic feelings (feeling hurt, victimized, neglected, unfavored), which served to camouflage sadistic impulses. These feelings, however, were also unsatisfactory in that she felt that they would upset other people as they had upset her father, who sometimes lost control of his sadism. Thus, she could not express either sadistic or masochistic impulses comfortably and shifted between them, using each tendency to undo the other. The result was turmoil and confusion, and she was sometimes unable to focus her thoughts. She also felt vulnerable to criticism, since she was unable to defend herself against others.

Mrs. C's sexual frigidity may be related to her difficulties with aggression: Since she could not comfortably disengage herself from other

people, sexual intimacy could be a problem in that she did not have the means of ending the closeness when she wanted to. Thus, an impairment in Type D behaviors could produce a corresponding impairment in Type C behaviors.

It was therefore hypothesized that during the treatment, Mrs. C first had to develop a better capacity to defend herself against other people (stubbornly resist other people without feeling guilty, disagree with other people, etc.) to allow herself to get closer to other people. It was hypothesized that as she acquired a better capacity for Type D behavior, she would feel less vulnerable in expressing Type C behavior and would therefore express Type C behaviors more freely.² The following procedure was designed to test these hypotheses.

Procedure. The first step was to examine Mrs. C's ability to express behaviors of Type D comfortably. A prominent subset of Type D behaviors contained instances in which she blamed, criticized, disagreed with, or opposed another person (the therapist or someone else). Three clinicians independently read the process notes of the first 100 hours in unsystematic order to avoid bias, looking for all passages in the notes that described such behaviors (in the present or in the past, toward the therapist or anyone else). Then the three clinicians together reviewed all of the passages that they had identified and retained the ones that they agreed were instances of blaming, criticizing, disagreeing, or opposing. Their resulting set contained 190 passages, involving both direct behaviors (e.g., criticizing the analyst) and self-reports of such behaviors.

Then a 4-point rating scale was developed to assess the directness of the behavior described in each passage. If the blame or criticism was only implied or if it was expressed tentatively with extreme discomfort, the scale value was 1; as the behavior became more explicit and direct, the scale value increased. A rating of 2 meant that a Type D behavior was expressed but immediately undone. Ratings of 3 and 4 meant that a Type D behavior was overtly expressed—3 by telling a third party about it, and 4 by directly

² It might be noted at this point that during the first 100 hours of treatment (covering a period of approximately 6 months), Mrs. C did achieve an increased, though limited, capacity to respond sexually. She also became more able to free associate easily, to reveal symptoms and preoccupations, and to think and work more productively. She became more able to express and tolerate strong feelings and found herself exercising a better-modulated discipline over the students in her class.

Figure 1. Mean rating of passages in each block of hours.

confronting the offending party. Each rating was also increased by .5 if the event occurred in the present tense (after the treatment began). Thus, the possible ratings were 1.0, 1.5, 2.0, . . . , 4.5.

The passages were divided into two subsets, and the passages of each subset were presented independently in random order to four clinical psychologists who were naïve about the case. Explicit scoring rules were developed for rating the passages, and the judges followed these rules in rating each behavior.

The second major step was to follow a similar procedure for identifying and rating the Type C behaviors. A prominent subset of these included behaviors in which the patient complimented someone, felt affection or compassion for someone, or wanted to be loved by someone. Two clinical psychologists read the process notes of the first 100 hours in unsystematic order looking for all passages in the notes that described such behaviors. As with the Type D passages, the clinicians reviewed the passages that they had identified and retained the ones that they agreed were instances of Type C behaviors. The resulting set contained 106 passages.

A 4-point rating scale was also developed to assess the directness of these behaviors. If the closeness was implied or expressed with extreme uncertainty, lack of clarity, or discomfort, the scale value was 1. A rating of 2 denoted an expression of closeness with immediate undoing.

As the behavior became more explicit and direct, the scale value increased: 3 indicated that the feeling of closeness was expressed to a third party, and 4 indicated that it was expressed directly to the other person. Each rating was also increased by .5 if the event occurred in the present tense (after the treatment began). The possible ratings thus ranged from 1.0 to 4.5.

These passages were also presented to a panel of four clinical psychologists who were naïve about the case. Explicit scoring rules were developed for rating the passages, and the judges followed these rules to rate each behavior.

Results

Type D behaviors. To assess the reliability of the judges' ratings, the four ratings for a given passage were averaged, and the reliability of the four judges' means was computed for each set through an analysis of variance. The reliability was .89 for one set, .90 for the other set.

The 100 sessions were then grouped into 10-session blocks denoted I, II, III, . . . , X. The number of passages within each block were I = 31; II = 13; III = 18; IV = 9; V = 35; VI = 13; VII = 13; VIII = 10; IX = 29; and X = 19. The ratings of passages within each block were averaged, and the means ranged from 2.62 to 3.81. These means are reported in Figure 1, which shows the development of Type D behavior across successive blocks of sessions.

To examine changes in Type D behaviors more closely, all passages rated alike were examined as a group. Because of the small frequencies in some categories, passages rated 2.0 and 2.5 were combined, as were passages rated 4.0 and 4.5. Also, to obtain more stable frequencies, the sessions were grouped into 20-session blocks.

The relative frequency of each rating was computed for each block, and these relative frequencies are shown in Figure 2. The top two graphs show a monotonic decline for passages rated 1.0-2.5. Figure 2 also shows a decline in 3.0s (criticizing someone for a past event) but an increase in 3.5s (criticizing someone for a current event). Direct confrontations (4.0 and 4.5) also became more frequent throughout the treatment. The graphs are largely monotonic and characterize major changes that occurred in the patient's behavior during the treatment.³

³ These graphs, of course, are not independent of one another. The overall improvement in Figure 1 requires that the lower ratings generally decline over the 100 hours while the higher ratings generally increase.

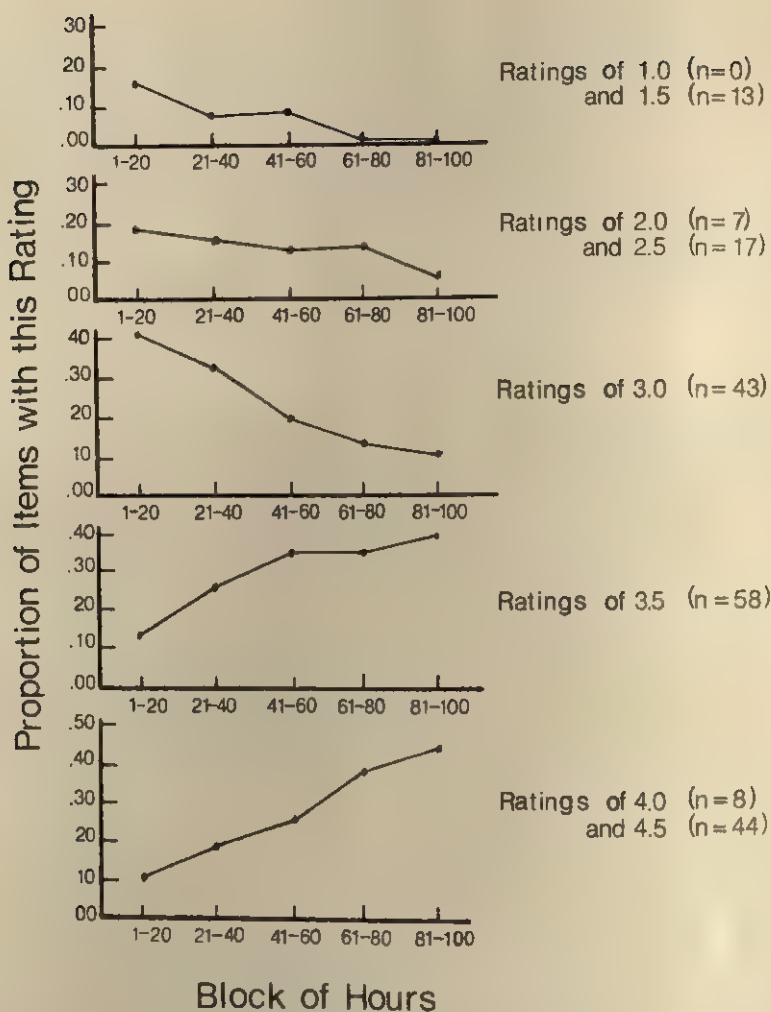

Figure 2. Relative frequency of passages in each rating category for successive blocks of hours (Type D).

To compare the frequencies of past and present events, the relative frequencies of 3.0s and 3.5s were compared. There were 101 passages with these ratings. For each block of 20 sessions, the relative frequency of 3.5s (present tense) was computed. For successive 20-session blocks, the values were 6/24 (i.e., 6 cases were in the present tense, 18 were in the past tense) = .25; 8/16 = .50; 17/26 = .65; 8/11 = .73; and 19/24 = .79. Thus, the patient increasingly came to criticize others for events in her current life. It is assumed that events from the past tense were less threatening for her and provided a convenient starting point for the therapy, but as the sessions progressed, she shifted her focus to her current life. Thus, *part* of the increment in Figure 1 is

due to the patient's shift to present tense events, and *part* is due to the decline in lower ratings (primarily 1.5 and 2.5).

Type C behaviors. The reliability of the 106 Type C ratings was also assessed. The four judges' ratings for a given passage were averaged, and the reliability of the four judges' means was .83. The 100 sessions were grouped into 10-session blocks, with the following frequencies within each block: Block I = 11; II = 9; III = 15; IV = 10; V = 9; VI = 12; VII = 14; VIII = 9; IX = 5; X = 12. The ratings of the passages within each block were then averaged, and the resulting means ranged from 2.67 to 3.75. Figure 1 shows the development of the Type C behaviors across successive blocks of sessions.

To examine the change in Type C behaviors more closely, passages within each rating category were examined separately. Since the frequencies were smaller than those concerning Type D behaviors, all of the ratings from 1.0 to 3.0 were pooled (These were the categories that had shown declining relative frequencies in Type D behaviors.); likewise, all of the ratings from 3.5 to 4.5 were pooled. (These were the categories that had shown increasing relative frequencies in Type D behaviors.) Relative frequencies of occurrence were computed for each block of 20 sessions, as shown in Figure 3. One graph shows a progressive decline in the relative frequencies of the lower ratings, and the other graph shows a progressive increase in the relative frequencies of the higher ratings. The two graphs thus resemble those obtained for the Type D behaviors. Events in the past tense were also examined, but their frequencies were too small (only 23 cases) to permit any inference.

Thus, it is clear that two types of changes occurred, but it still needed to be demonstrated that a change occurred in the patient's presenting complaint, sexual frigidity. Therefore, every reference to the patient's sexual behavior was noted throughout the 100 hours. There were 18 such references (comprising a subset of the 106 Type C passages), all occurring between Hours 28 and 100. Each passage contained the word *intercourse* except one, which contained the phrase *sexual interest*. Here are some examples: From Hour 33 (rated 2.5): "Sometimes when she is trying to make herself have intercourse with Bill, she feels as though she wants to hurt him. She just doesn't understand it. She'll go from feeling very warm to feeling nothing toward him suddenly." From Hour 67 (rated 4.5): "This weekend she and Bill had intercourse, and she was thinking how different it can be when she's thinking about him and feeling close to him and not all wrapped up in herself."

Seven passages occurred in the first 50 sessions, and 11 occurred in the last 50 sessions. The C rating assigned to each passage was noted. For those in the early block, 6 had ratings of 1.5 to 2.5, and 1 (in Hour 43) had a rating of 3.5 to 4.5. Of the 11 passages in the later block, 4 had ratings of 1.5 to 2.5, and 7 had ratings of 3.5 to 4.5. The 7 passages with high ratings were mainly simple, direct statements that the patient had had sexual intercourse. A Fisher exact test was performed to test the significance of this difference; the chance probability of the observed pattern or a more extreme one is .022.

Figure 3. Relative frequency of passages in different rating categories for successive blocks of hours (Type C).

Observation 2: Relationship Between C and D Behaviors

The capacities to express C and D behaviors comfortably seem to be related, since a defect in D can produce a corresponding defect in C. That is, if a person did not have the capacity to disengage from the other person, intimacy would be unsafe, since the person would not be able to end the closeness and would run the danger of feeling oppressed or entrapped. On the other hand, once the person gained the capacity to express D behaviors comfortably, closeness would not be as threatening.

Thus, as Mrs. C gained the capacity to express Type D behaviors comfortably, it should become easier for her to express Type C behaviors. In any block of therapy sessions in which significant gains are observed in Type D behaviors, improvement should subsequently be observed in Type C behaviors. This hypothesis is examined below.

Method, Results, and Discussion

In Figure 1 the C graph resembles the general form of the D graph. To examine the relationship between the graphs more closely, the posi-

tions of greatest increase along each graph were noted. A "significant improvement" in either function is defined as an increment from Block i to Block $i + 1$ that exceeded .25. Significant improvements in Type D behavior occurred three times—from Block II to Block III, from Block III to Block IV, and from Block V to Block VI. Furthermore, significant improvements in Type C behavior also occurred three times—from Block III to Block IV, from Block IV to Block V, and from Block VI to Block VII. In each case, a significant improvement in Type C behavior followed a significant improvement in Type D behavior: An improvement in D occurred from II to III, an improvement in C occurred from III to IV. The chance probability that the three Type C improvements would occur in these particular three positions is .012.

In addition, a "setback" in either function is defined as a decrement from Block i to Block $i + 1$. A setback in the Type D behavior occurred three times—from Block I to Block II, from Block IV to Block V, and from Block VI to Block VII. A setback also occurred three times in the Type C behavior—from Block II to Block III, from Block V to Block VI, and from Block VII to Block VIII. Thus, a setback in Type C behavior always followed a setback in Type D behavior. In other words, the two graphs took very similar courses, with one displaced from the other by one block of sessions.

The data therefore suggest that the patient's progress in expressing Type C behaviors followed her progress in expressing Type D behaviors. As she became progressively able to criticize, oppose, and disagree with other people, she felt progressively less vulnerable; then, feeling less vulnerable, she could relax her defenses and permit herself to feel close, affectionate, and compassionate toward other people. If the two graphs had simply exhibited a correlation, other factors could account for their concomitant rise and fall. But their displacement in time suggests that an advance in one type of behavior may have facilitated an advance in the other.

This inference must be made with reservations for three reasons. First, the relationship may only describe an idiosyncrasy of one patient's progress and needs to be replicated with other cases. For example, Mrs. C's progress in part reflected a shift from past to present tense, and her proportions of present tense passages throughout the treatment, while similar for C and D behaviors, were not identical. It is possible that combining nonuniformities of this type could produce a lag between two graphs. Such issues would be best resolved by replicating the findings on another case.

Second, changes in Type C and Type D behaviors, as operationalized here, may be trivial. That is, they may reflect changes that occur in any developing human relationship in the way that the partners relate to each other (talking more directly, less cautiously, less formally) and are thus not necessarily to be traced to the therapy itself. It is possible that whenever Mrs. C entered a new relationship with someone, she would initially qualify with great caution any statements that she made so as to present a balanced view on any subject; such a tendency would involve statements that would get lower ratings. Then, as she came to know the other person better, she might drop this tendency and become more direct. If this interpretation were correct, though, C and D changes should occur simultaneously, rather than one consistently lagging behind the other.

Finally another kind of explanation might account for the observations in Figure 1. Suppose the direct expression of aggression is in some sense incompatible with the direct expression of intimacy, so that the relative prominence of one would imply a relative decline in the other. Then, as one graph rose from Block i to Block $i + 1$, the other graph would fall. For example, in Figure 1, from Block I to Block II, the C graph rises while the D graph falls, causing the graphs to cross. Then, proceeding to Block III, the C graph falls while the D graph rises, producing another crossing. Additional crossings occur as the graphs proceed to Blocks V, VI, VII, and VIII. This characterization of the data has the virtue of parsimony, but it does not explain why both graphs would show concomitant overall improvement. It also suggests that the frequency of Type D behaviors should be strongly and negatively related to the frequency of Type C behaviors. The correlation was negative, but it was not significant ($r = -.33, p > .20$).

Thus, alternative hypotheses may account for some aspects of the data, and perhaps may even accurately account for aspects of the therapeutic process. However, they do not adequately explain the lag between graphs or the overall improvement in each type of behavior. For this reason, it is tentatively concluded that improvement in Type D behavior, at least in this patient, permitted subsequent improvement in Type C behavior.

Observation 3: The Nature of Mrs. C's Complaints

In the courses of 100 hours of treatment, Mrs. C mentioned a large number of other problems

that were not directly related to sexual frigidity but that clarify the nature of her distress. Many of these complaints were expressed in the form "I can't (do something)" or "I have to (do something)," revealing inhibitions and compulsions. A large subset of these complaints could be classified according to the C and D categories, and it was hypothesized that many complaints would reflect general problems over C and D behaviors.

Two people reading the process notes independently identified 248 complaints involving "can't" (e.g., She can't praise her assistant) and 103 complaints involving "has to" (e.g., She has to fight against her husband), making a total of 351 complaints.⁴ Near symptoms of *can't* and *has to* were also accepted.

The statements were presented to a group of 20 judges (10 graduate students and 10 clinicians). Each judge was asked to classify each problem behavior as to Type C, Type D, or neither. A statement was considered a Type C or Type D complaint if 14 or more judges so classified it. Using this 14-or-more criterion, 60 complaints were of Type C and 56 were of Type D.

The complaints of each type were then examined further to determine how many were of the *can't* form and how many were of the *has to* form. Of the 60 Type C complaints, 51 were of the *can't* form and 9 of the *has to* form. Of the 56 Type D complaints, the corresponding frequencies were 24 and 32. The chi-square computed for this 2×2 matrix was 20.7 ($p < .001$). Whereas Type C complaints were typically of the *can't* form, Type D complaints were more evenly divided between the two. The single highest frequency was for complaints of the form "*can't C*," a form that corresponds to the presenting complaint, sexual frigidity.⁵ The other complaints, involving aggression and assertiveness, reflected poor control both ways: Sometimes the patient could not express behaviors that she wanted to express, but at other times she could not restrain herself.

General Discussion

Sophisticated studies of psychotherapy outcome have been undertaken in recent years, as summarized in the recent review of Bergin and Suinn (1975). Most of these studies (e.g., Berzins, Bednar, & Severy, 1975; Sloane et al., 1975) have reported data about treatment outcome, though details of the therapeutic process remain generally unclear. The present set of studies, in contrast, focuses on the treatment process per se and assumes that therapeutic out-

come is best evaluated in the light of one patient's needs and goals.

The present article has examined several explicit propositions about the nature of Mrs. C's psychopathology and therapeutic progress. One major result showed that Mrs. C's difficulty in expressing Type C behavior was related to her difficulty in expressing Type D behavior; thus, the way to solve one specifiable set of problems involved the simultaneous treatment of another set. Throughout the treatment, progress on one set was a prerequisite for concomitant progress on the other.

These results thus point out one feature of a therapeutic process that is often overlooked in treatments that set more specific behavioral goals, namely, that an advance in one behavioral domain may be a prerequisite for an advance in another, quite different, domain. For a patient like Mrs. C, a gain in assertiveness may be necessary for a gain in intimacy. Occasional writers have implied such a relationship (e.g., Smith, 1975), but no systematic documentation or explanation of the relationship has previously been offered.

Furthermore, in Mrs. C's treatment, there were really two major therapeutic goals, but only one corresponded to her presenting complaint (sexual frigidity). It is possible, of course, that Mrs. C would have been helped more efficiently by a combination of assertiveness training and sexual therapy, but it is not necessarily the case that she perceived herself as needing to become more assertive. Indeed, a tabulation of her complaints throughout the first 100 hours showed that she often found herself too aggressive and oppositional, more than she wanted to be. Nonetheless, in principle, one could imagine a research design with patients like Mrs. C, comparing each kind

⁴ These various complaints declined in frequency over the 100 hours. The relative frequencies occurring in successive 20-session blocks were .26, .24, .17, .19, .15; $\chi^2(4) = 15.48$, $p < .01$.

⁵ Very few of these *can't C* complaints were specifically sexual in content, however. They concerned various people—the patient's husband, therapist, pupils, assistants—and they involved various forms of closeness—giving unilaterally to other people (praising, helping, reassuring, comforting, disclosing personal information), as well as exchanging (relating to other people, trusting, believing, returning love, feeling close to or relaxed with). The Type D problem behaviors were also heterogeneous, involving assertiveness (getting her own way, sticking to her views, developing her own teaching method, making demands on other people, disagreeing with other people) and aggression (expressing anger, being nasty to people, criticizing other people, opposing other people).

of treatment singly and in combination with the other kind of treatment.

One early theme in Mrs. C's therapy consisted of her criticizing people (e.g., her parents) for events of the past. This kind of theme often occurs early in a treatment as the patient spontaneously produces data from the past. It is possible that Mrs. C saw as one demand characteristic of therapy that she criticize her parents for events of the past. In our view, however, she was not only producing personal data but was also serving very specific therapeutic ends by beginning the treatment in this way. Her criticisms allowed her to observe the therapist's reaction to one very mild form of aggression and assure herself of the safety of similar undertakings in the future. This low-level criticizing can be viewed as an early test of a therapist. Other evidence of such tests has been presented by Horowitz, Sampson, Siegelman, Wolfson, and Weiss (1975).

Finally, the distinction between C and D behaviors emphasizes the *meaning* of the behavior in addition to its observable form. A given behavior may have multiple meanings for a particular person. For example, the very same behavior might be of Type D with respect to one person and of Type C with respect to another person. A criticism rated 3 in this study would be such a case; it was of Type D with respect to the criticized person and of Type C with respect to the therapist (since the patient is confiding in or confessing to the therapist). This form of closeness to the therapist was never tabulated among the Type C behaviors of this study, but it may comprise a significant aspect of the

therapeutic process: The patient criticizes a third person, tentatively viewing the therapist as an ally; then, when the therapist permits the alliance, a closeness is established between them that neither party has directly solicited. Such aspects of the therapeutic process need to be examined further.

Brief Reports

Locus of Control, Prediction, and Performance on University Examinations

Timothy M. Gilmor and David W. Reid
York University, Downsview, Canada

Fifty-two internal and external locus of control subjects estimated what their outcomes would be for two term exams and their final grade. Internals' estimates and actual outcomes tended to be higher than those of externals. Accuracy of predictions as assessed by difference scores did not differentiate the two groups. However, internals' estimates from the first to second exam were characterized by more typical expectancy shifts demonstrating a greater responsiveness to their initial performance feedback.

Research on the locus of control construct (Rotter, 1966) has shown that internals compared to externals obtain higher grades (Brown & Strickland, 1972) and make more accurate predictions for self-relevant achievement outcomes (Steger, Simmons, & Lavelle, 1973; Wolfe, 1972). However, the former relationship has been found more consistently for younger samples than for older samples (Gilmor, 1978; Phares, 1973), and some research demonstrating the latter relationship has been criticized on methodological grounds (Wolfe & Egelston, 1973).

The present study extends prior work by examining both the actual performance of internal and external university students and the accuracy of their predictions over several term exams as well as the final grade. A more thorough examination of the relationship was possible by broadening the sample of behavior (three outcome events rather than one) and by incorporating additional dependent measures assessing the nature of internals' and externals' predictions. In addition to assessing the accuracy of predictions by means of difference scores, the percentage of overestimates versus underestimates and typical versus atypical expectancy (estimate) shifts from the first to second exam were calculated.

Prior research (cf. Strickland, 1977) has found

that internals exhibit more typical expectancy shifts (increase in expectancy after success, decrease in expectancy after failure), whereas externals exhibit more atypical expectancy shifts (increase in expectancy after failure, decrease in expectancy after success). This pattern of expectancy shifts was expected to occur in the present context and to provide support for the contention that internals are more responsive to the feedback that they receive in making predictions for future performance. No specific prediction was made concerning the proportion of overestimates versus underestimates for each group.

Subjects were 20 male and 32 female undergraduates in a third-year psychology course. Several weeks after the class had begun, the first of several questionnaires was administered. Information sought included: "How many university exams or term tests have you written?" "What is the final grade you expect to get in this course?" and, "It is early to predict, but how well do you think you will do on the first exam in this course? ____/100."

One week later the class completed an expanded version of the Reid and Ware (1974) multidimensional Locus of Control scale. A median split of scores on the Fatalism subscale determined the internal (0-6) and external (8-18) groups. Subjects with scores at the median were eliminated.

After the first exam results were made known to the class, a "follow-up" questionnaire was administered asking subjects to report their exam result and to predict what their second exam result would be (scheduled for 4 weeks later). At the end of the term, their second exam results and

Completion of this study was facilitated by a Canada Council doctoral fellowship granted to the first author.

final grade were obtained for comparison to their predictions.

An initial analysis revealed no main or interaction effects due to high versus low exam experience (cf. Wolfe, 1972). Overall, the group had considerable previous exam writing experience ($M = 14.46$). Consequently, 2×2 (Sex \times Fatalism) analyses of variance were conducted on the (a) performance estimates, (b) actual results, and (c) difference scores for each exam and the final grade. Chi-square analyses were conducted on the frequency of overestimates versus underestimates and typical versus atypical expectancy shifts.

For the first exam, the estimates of internals ($M = 75.9$) were marginally higher than the estimates of externals ($M = 72.6$), $F(1, 48) = 2.56$, $p < .15$. The actual first-exam performance of internals ($M = 76.9$) was significantly higher than that of externals ($M = 64.0$), $F(1, 48) = 11.02$, $p < .01$. For the second exam, a significant difference was found between internals' ($M = 77.1$) and externals' ($M = 72.0$) estimates, $F(1, 48) = 6.54$, $p < .05$. However, only a marginal difference, $F(1, 48) = 2.40$, $p < .15$, was obtained for internals' ($M = 66.1$) versus externals' ($M = 60.6$) actual performance.

With respect to the final grade, no differences were found between the different groups' estimates, $F(1, 48) < 1.00$, $p > .25$, although internals ($M = 4.0$) compared to externals ($M = 5.1$) obtained higher final grades, $F(1, 48) = 5.00$, $p < .05$. The numerical means approximate a grade letter of B for internals and C for externals. Both groups had initially estimated that they would achieve a grade of B+.

Analyses of the difference scores for each exam and the final grade revealed no sex or locus of control differences.

Analysis of the percentage of overestimates versus underestimates for both exams combined revealed that externals (78.6%) more frequently overestimated their upcoming exam result than did internals (60.4%), $\chi^2(45) = 4.92$, $p < .05$.

Consistent with the above results and with prior research was the finding that the expectancy shifts of internals (62.5%) were more frequently typical (vs. atypical) than those of externals (42.8%), $\chi^2(42) = 3.98$, $p < .05$. That is, internals more frequently raised their estimates for the second exam if expectancies for the first exam had been surpassed, and they lowered their estimates for the second exam if expectancies

for the first exam had not been met. Externals did the opposite; they more frequently raised their expectancies for the second exam despite poorer-than-expected performance on the first exam and lowered their expectancies for the second exam despite better-than-expected performance on the first exam. These results support the theoretical contention that externals are not as responsive as internals to initial feedback in making estimates for future performance.

Although internals and externals in this sample were not differentiated in terms of the accuracy of their predictions, their predictions did differ qualitatively in terms of the frequency of overestimations and typical expectancy shifts. Also, the finding that internals attained higher performance outcomes suggests that the locus of control/academic achievement relationship so often found in studies with children also holds for adult samples.

Person \times Situation Interaction in Personality Prediction: Some Specifics of the Person Factor

Lawrence J. Breen
University of Manitoba

Terry J. Prociuk
University of Manitoba
Winnipeg, Canada

Norman S. Endler
York University
Toronto, Canada

Marilyn Okada
York University
Toronto, Canada

This study attempted to determine if the multidimensionality of trait anxiety (A-Trait), as measured by the S-R Inventory of General Trait Anxiousness, was related to differential personality profiles. Results of stepwise multiple linear regression analyses, using the Internal-External Locus of Control Scale, the California Psychological Inventory, the Fear of Negative Evaluation Scale, and the Interpersonal Trust Scale as predictor measures, confirmed the existence of distinct personality profiles for each of the four facets of A-Trait. These findings attest to the multidimensionality of the S-R Inventory of General Trait Anxiousness and to the importance of specifying the situation in the measurement of anxiety.

Recently, Endler and Okada (1975) discussed the limitations of many existing omnibus measures of anxiety proneness (A-Trait). At the same time these researchers provided data supporting their claim that the S-R Inventory of General Trait Anxiousness offers a more appropriate assessment of A-Trait. This inventory is a multidimensional measure of anxiety (e.g., Endler & Magnusson, 1976; Endler, Magnusson, Ekhammar, & Okada, 1976) that provides indices of anxiety responses to situations involving interpersonal relations, physical danger, ambiguity, and generally innocuous conditions.

The purpose of this study was to determine if the multidimensionality of the Endler-Okada inventory would be reflected in differential personality profiles. These profiles were to be derived from a battery of personality tests administered with this inventory and were expected to be logically and theoretically consistent with the four situational dimensions of anxiety ostensibly assessed by the S-R Inventory of General Trait Anxiousness.

Subjects were 278 senior-year, female nursing students in training at 13 institutions in the province of Manitoba, Canada. The subjects were

administered a personality battery that consisted of the 18 scales of the California Psychological Inventory (CPI; Gough, 1957). The CPI seeks to measure interpersonal facets of personality such as sociability and self-control. They were also given the Internal-External Locus of Control Scale (Rotter, 1966); the Interpersonal Trust Scale (ITS; Rotter, 1967); the Fear of Negative Evaluation scale (FNE), developed by Watson and Friend (1969); and the S-R Inventory of General Trait Anxiousness (Endler & Okada, 1975). Obtained data were subjected to separate stepwise multiple linear regression analyses with the four S-R situation scores used as the criterion variables.

For parsimony of results only those variables that related significantly ($p < .05$) to the S-R situation scores and yielded a multiple correlation change equal to or greater than .01 are discussed. There were additional variables whose statistical contributions were significant but whose practical contribution was negligible (i.e., multiple correlation change $< .01$).¹

With these considerations in mind, it was found that scores on the interpersonal facet of A-Trait (i.e., you are in situations involving interactions with other people) were negatively related to scores on the CPI measures of intellectual efficiency, sociability, self-acceptance, and

The authors would like to thank Helen P. Glass, Director of School of Nursing, University of Manitoba, for making the data collection possible.

¹ Complete data summary tables are available from the first author on request.

good impression ($R = .55$, $p < .05$). High scores on the physical danger facet of A-Trait (i.e., you are in situations where you are about to or may encounter physical danger) were associated with low scores on two measures (CPI scale of good impression and ITS and with high scores on the CPI Sociability scale ($R = .34$, $p < .05$). For subjects expressing anxiety on the ambiguous facet of A-Trait (i.e., you are in a new or strange situation), there was a negative association with their scores on the CPI measures of sociability, capacity for status, and good impression. These same individuals obtained high scores on the FNE scale and low scores on the CPI measure of flexibility ($R = .54$, $p < .05$). For the innocuous facet of A-Trait (i.e., you are involved in your daily routines), the scores were negatively related to scores on the CPI measures of intellectual efficiency and achievement via conformance ($R = .34$, $p < .05$).

Independence among the four scales of the S-R inventory can be inferred from the distinctions among the predictive regression equations and also (of course) from the correlations among the parts. With respect to the latter, the correlation coefficients were low and ranged from $-.04$ to $.21$ for physical danger versus innocuous and ambiguous versus innocuous, respectively.

In summary, the obtained results strongly suggest the existence of separate personality profiles for the four facets of A-Trait. Furthermore, it is evident that these profiles are logically congruent with the type of situation described. For example, it is reasonable to expect that individuals who express anxiety in an interpersonal situa-

tion should score low on measures of sociability, self-acceptance, good-impression, and so on. Similarly, persons who feel anxious in unfamiliar, ambiguous situations might well indicate a lack of flexibility and a concern over social evaluation. In sum, the data tend to form patterns that are consistent with the claim for the multidimensionality of the S-R inventory.

Abnormality of Subtest Score Differences on the WISC-R

Richard J. Piotrowski
Allegheny Intermediate Unit #3
Pittsburgh, Pennsylvania

The abnormality of the difference as a method for evaluating the magnitude of differences between pairs of Wechsler Intelligence Scale for Children-Revised subtests is discussed. Generally, abnormal differences at the .05 level of significance range from 6 to 7 scaled score points and 8 to 10 scaled score points at the .01 level. Abnormal Verbal-Performance scale IQ differences are also considered. Such differences averaged 18 IQ points at the .05 level of significance and 24 IQ points at the .01 level. The diagnostic implications of the use of the abnormality of the difference for evaluating subtest score differences are discussed.

The evaluation of differences between subtest scores is a common problem for the users of tests such as the Wechsler Intelligence Scale for Children-Revised (WISC-R). Unfortunately, the magnitude of subtest score differences has too often been evaluated on the basis of clinical intuition or on the recommendations of test publishers without an adequate statistical basis for such recommendations.

When a statistical answer to this problem has been given, it has generally involved computing the standard error of measurement of the difference between subtest pairs. Using this approach, the WISC-R manual (Wechsler, 1974) provides a table of significant subtest score differences based on the average values for all 11 age groups included in the standardization sample. Using the rather weak .15 level of significance, differences of only 2.35-3.45 scaled score points between subtests are considered significant. Using the more conventional .05 and .01 levels of significance and considering age levels separately, it was found that 3-5 points at the .05 level and 4-6 points at the .01 level were generally required for significance (Piotrowski & Grubb, 1976; Sattler, 1974).

Another way of statistically evaluating subtest score differences, the abnormality of the difference, was suggested by Silverstein (1973). While the standard error of measurement of the difference indicates how large a difference must be so that it cannot be attributed to measurement

error, this other method reveals how large of a difference must exist for there to be little chance of it occurring in a normal population (Silverstein, 1973).

The abnormality of the difference (A_d) can be computed using the following formula:

$$A_d = z\sqrt{\sigma_1^2 + \sigma_2^2 - 2r_{12}\sigma_1\sigma_2}$$

where σ_1 and σ_2 are the standard deviations of the subtests being compared, r_{12} is the intercorrelation between these two subtests, and z is the probability level that was used.

The present investigation involved computing the abnormality of the difference between all possible pairs of the 12 WISC-R subtests at each of the 11 age levels included in the standardization sample. Differences between Verbal and Performance scale IQs were also examined. The necessary standard deviations and intercorrelations were obtained from the WISC-R manual (Wechsler, 1974).

For a difference between any two WISC-R subtests to be considered "abnormal," a 6- or 7-point difference is generally required at the .05 level of significance, whereas an 8- to 10-point difference is typically required at the .01 level. Abnormal Verbal-Performance scale IQ differences averaged 18 points at the .05 level of significance and 24 points at the .01 level.

When compared to the size of differences generated by the standard error of measurement of the difference, the abnormality of the difference resulted in subtest scaled score differences for similar comparisons that were generally 2 or 3 points higher at the .05 level and 3 or 4 points higher at the .01 level. Abnormal Verbal-Performance scale IQ differences were 5-8 points higher at the .05 level and 8-10 points higher at

Requests for reprints and for an extended report of this study should be sent to Richard J. Piotrowski, Allegheny Intermediate Unit #3, Suite 1300, 2 Allegheny Center, Pittsburgh, Pennsylvania 15212.

the .01 level than when the weaker standard error of measurement of the difference was used.

In light of the rather large discrepancy in the size of "differences" generated by these two indices, the implications of differences of varying magnitude should be considered. Test score differences falling short of the standard error of measurement of the difference may, of course, be attributed to measurement error or chance. A difference between two scores, which is significant in light of the standard error of measurement of the difference, suggests that there is a difference that can be reliably measured in the abilities or skills tapped by the tests being compared. Such differences may well have educational or program planning significance, since they point to "real" differences between the abilities measured by the subtests being compared. However, the fact that an individual's abilities are not uniformly developed should not be considered highly unusual. Only when the difference between scores reaches the magnitude of the abnormality of the difference might the scatter between an individual's abilities be considered unusual when compared to the amount of scatter generally found within the abilities of *other* individuals.

Two recent studies are relevant in regard to the size of differences obtained when using the WISC-R. Using data computed from the standardization sample of the WISC-R, Kaufman (1976a) found that rather large differences between subtest scores are typical. When all 12 WISC-R subtests were given, less than 30% of the normative population showed a difference of 6 or less points between their highest and lowest subtest scaled scores. At the same time, approximately 20% had differences of 9 points or more, 5% had differences of 11 points or more, and 2% had differences of 13 points or more.

A second study by Kaufman (1976b) revealed that rather large Verbal-Performance IQ scale differences were also typical of the standardization sample. Verbal-Performance IQ differences of 9 points or greater were found in 48% of subjects, 34% had differences of 12 points or more, and 25% had differences of 15 points or more.

At the .05 level, abnormal Verbal-Performance differences averaging 18 IQ points were found in the present study. Differences of this size or greater were found by Kaufman (1976b) in 12% of the standardization samples. Similarly, at the .01 level, abnormal Verbal-Performance differences averaged 24 points. Only 4% of the original sample had differences this large or greater.

In light of Kaufman's findings, it appears that the abnormality of the difference provides a statistic that is realistically related to the actual performance of children on the WISC-R. This close degree of correspondence between the abnormality of the difference and Kaufman's findings has important diagnostic implications. In regard to the identification of children who are expected to show a wide variability between their "peaks" and "valleys" (e.g., learning disabled), differences more in line with the magnitude of the abnormality of the difference or greater might be expected. Similarly, the tolerance for the spread of abilities in children seen as potential candidates for programs characterized by a "flat" ability profile (e.g., educable mentally handicapped, slow learners) might be extended to just short of the point generated by the abnormality of the difference.

Correlation of WAIS IQ in 10 Pairs of Brothers

Joseph D. Matarazzo and Arthur N. Wiens
University of Oregon Health Sciences Center

Allen E. Shealy
University of Alabama in Birmingham

Ten pairs of brothers with a mean age of 24 years and a mean of 13 years of education were individually examined with the Wechsler Adult Intelligence Scale some 10 months apart by a highly experienced clinical psychologist who was unaware of the consanguineous relationship. The obtained correlation of .42 for Full Scale IQ is consistent with the median correlation of .49 reported by Erlenmeyer-Kimling and Jarvik in their 1963 review of the world's literature.

The relationship between consanguinity and measured intelligence was the focus of active investigative interest between 1910 and 1950, with the results reported in the world's literature succinctly summarized in a review by Erlenmeyer-Kimling and Jarvik (1963). Inasmuch as the Wechsler scales had not yet been developed during the period when most of these studies were being conducted, we were curious as to whether the post-1940 studies on the relationship between IQ in siblings had ever used Wechsler's measures. In their review Erlenmeyer-Kimling and Jarvik reported 35 studies of siblings reared together and 2 studies of siblings reared apart. At our recent request, they kindly sent us their bibliographic references for each of these 37 studies plus a summary list of the intelligence tests used by each of the investigators.

Their list revealed that the 37 sibling studies had been reported in 31 different publications between 1912 and 1962 and that a total of 15 different tests had been used in 37 sets of combinations. Additionally, 4 of the 37 studies failed to identify which test(s) yielded the sibling correlation reported. Not surprisingly for this early era, the test most frequently used in studying the correlation between IQs of siblings was the Stanford-Binet (13 studies). This test was followed by the Otis (6 studies), Army Alpha (4 studies), the Terman Group Test (2 studies), and the National Intelligence Test (2 studies). Finally, each of the following tests were used in 1 study: Army Beta, IER Test of Selective and Rational

Thinking, South Africa Group Intelligence Tests, Vocabulary tests from the University of Minnesota College Aptitude Test, Haggerty Intelligence Examination, College Entrance Test, Cattell scales, Pintner Rapid Survey Intelligence Test, Test mosaïque de Gille, and the CVB (Swedish abbreviated Wechsler-Bellevue). It is clear from this that excluding the Stanford-Binet, many of these tests are paper-and-pencil instruments that were designed for self or group rather than individual administration.

The background for the present article is that since 1959 we have been involved in a patrolman selection program for the city of Portland. The 6-hour patrolman examination includes a number of standard clinical psychological assessment instruments, one of which is the individually administered Wechsler Adult Intelligence Scale (WAIS). Noting recently that to date we had examined some 1,200 applicants between the ages of 21 and 31, we researched these records and found that 10 pairs of these applicants were brothers. Although relatively few in number, we decided to compute the correlation between pairs of WAIS scores on these 20 brothers for several reasons. First, because of the value of such data. As Alstrom (1961) has noted:

By comparison with the immense quantity of (intelligence) test investigations which have been carried out all over the world, there have been extremely few carried out on representative series of families. . . . Every such study of a representative sample of families is therefore of great value. (p. 199)

Second, as a test of measured intelligence, the WAIS is among the best such measures currently available. Third, unlike many studies of measured intelligence in families that individually examined (often using student examiners) the two family

members in one sitting and thus conceivably could introduce a bit of examiner halo effect or other bias, our "study" was neither planned nor were the siblings examined on the same day. That is, except for a single pair of fraternal twins among our 10 pairs who were examined on the same day, the WAIS examiner (ANW) for the present study, a board-certified clinical psychologist, did not know at the time he examined the second applicant that the applicant's brother also had been examined by him on a previous occasion.

After we identified them, the 10 pairs of brothers were divided into Group A (first brother) and Group B (second brother). Descriptive data for the day of examination for Group A and Group B yielded the following means and ranges (in parentheses), respectively: ages = 24.0 years (21-32) and 24.6 years (22-29), and education = 13.2 years (12-16) and 13.7 years (12-17). The interval between testing of Brother A and Brother B ranged from 0 to 83 months, with a mean of 17.4 months and a median of 10.5 months. Thus our study involved 10 pairs of 24-year-old brothers with a mean of 13 years of education who were individually examined with a median interval of 10 months by a highly experienced clinical psychologist who was unaware of the consanguineous relationship.

Followers of Pearson's studies on sibling correlation are aware that in his research he computed a double-entry Pearson correlation, entering each pair of scores twice; first as XY then as YX. His procedure yielded the following values for our data: $r_s = .31, .05$, and $.48$ ($p = .02$), for Full Scale IQ, Verbal IQ, and Performance IQ, respectively.

We were less interested in such statistical sophistication, being more interested here in a standard Pearson correlation to satisfy our clinical curiosity as to what value it would reach for the WAIS given to 10 pairs of brothers. The value of the standard Pearson correlation that we obtained for the Full Scale IQ was $.42$. Although

a bit short of statistical significance with our N of 10 pairs, this is a value not unlike the median correlation of $.49$ yielded in the 37 studies reviewed by Erlenmeyer-Kimling and Jarvik (1963) despite the fact that our 20 subjects earned IQs only in the top 50% of the range (i.e., from a low Full Scale WAIS IQ of 105 to a high of 126, with a mean of 112.6 for Group A and a mean of 115.2 for Group B). The corresponding correlation for Verbal IQ of our 10 pairs was $.12$ and for Performance IQ was $.54$. Other than small sample size, we could find no explanation in our data, such as one or two deviant cases, to explain this lower correlation for Verbal IQ.

The data from the 13 studies that consisted of individually administered Stanford-Binets were probably the most robust among the 37 studies in the review by Erlenmeyer-Kimling and Jarvik (1963). The correlation of $.42$ for Full Scale IQ obtained by us with the equally robust WAIS in these 10 pairs of adult brothers adds one additional datum, suggesting that the median correlation of $.49$ for siblings in the 37 studies reviewed by Erlenmeyer-Kimling and Jarvik is a reliable value. This latter interpretation is especially important inasmuch as our examiner was unaware that he was examining a sibling in all but one pair, and thus our gnawing concern since we began rereading this literature on a potential examiner halo effect in some of the earlier studies was put to rest by the results of the present study.

Self-regulatory Effects of Monitoring Sensory and Affective Dimensions of Pain

Kenneth D. Craig, Helen Best, and J. Allan Best
University of British Columbia, Vancouver, Canada

The differential effectiveness of focused attention on either affective-discomfort or sensory components of electric-shock-induced pain experiences was examined. In addition, the impact of models displaying tolerance or intolerance for pain was examined on reports of these different components of the experience. Attention to sensory components led to lower pain tolerance, avoidance of shocks at lower current levels, and characterizations of the shocks as more painful than stronger current intensities accepted during the discomfort rating task. The strategy of modeling tolerance was effective in influencing both sensory and affective reports of the experience.

Recent conceptualizations of pain experience distinguish between sensory-discriminative and affective-motivational qualities. Experimental and clinical research indicate that the discrimination between sensory qualities and affective attributes is readily accomplished. This study examined whether a potent form of social influence, exposure to tolerant or intolerant models, would differentially influence characterizations of physical as contrasted with affective qualities of pain experience.

The social context was expected to be a more potent determinant of characterizations of discomfort than physical qualities. This is because subjective discomfort appears to be more inclusive of various experiential components of pain than characterizations of physical qualities, since they are the product of sensory, affective, and contextual factors. In addition, reports of discomfort appear to have more important social functional value and, consequently, should reflect greater sensitivity to the social context.

The investigation also examined the effects of self-monitoring of either discomfort or physical intensity qualities on pain tolerance. Demonstration of differential attentional effects could have some impact on the choice of cognitive strategies to be used for the self-management of pain.

Subjects were 30 male undergraduate student volunteers. They participated in sessions with a

male model portraying a naive subject. He did not receive shocks, and his ratings were based on subjects' responses. Subjects were assigned randomly to one of six groups based on a 3×2 factorial. The first variable concerned whether the model assumed the role of a tolerant or intolerant companion also subjected to shocks or an inactive observer. The second variable was based on the two possible sequences of rating the electric shocks on physical and discomfort intensity judgmental tasks.

Electric shocks of a 1-sec duration were generated by a 60-Hz stimulator and delivered through concentric electrodes to the volar surface of the right forearm. Three ascending series of shocks were delivered with each trial increasing by .5 mA until subjects reported that they could endure no further increases.

Rating scales were described to subjects that provided appropriate labels for characterizing the shocks in terms of either physical intensity or affective discomfort. For judgments of physical intensity, labels read *undetectable*, *low*, *moderate*, *high*, and *extremely high*. For discomfort ratings, labels were *not uncomfortable*, *uncomfortable*, *very uncomfortable*, *painful*, and *intolerable*. It was emphasized that the last switch was to be reserved for a current level beyond which they could endure no further shocks and that no shocks would be given after it was used. All subjects undertook both judgmental tasks in counterbalanced order.

The model enacted the intolerant role by remaining one label ahead of the subject on the intensity scale. The tolerant role was enacted by essentially having the monitor remain one label behind the subject.

Additional questionnaires required evaluations

This investigation was supported by research grants from the Canada Council.

Requests for reprints and for an extended report of this study should be sent to Kenneth D. Craig, Department of Psychology, University of British Columbia, Vancouver, British Columbia, Canada V6T 1W5.

of the shocks on intensity and discomfort dimensions and ratings concerning other aspects of the study.

Four-way analyses of variance were used to evaluate the effects of modeling, rating order, the two judgmental tasks, and the repeated shock series on pain tolerance. Significant differences were observed as a result of the two judgmental tasks, $F(1, 24) = 4.84$, $p < .05$, and the two modeling roles, $F(2, 24) = 4.75$, $p < .01$. Tukey (*b*) tests ($\alpha = .01$) indicated that the tolerant group accepted substantially greater shocks ($M = 10.41$ mA) than the intolerant group ($M = 6.68$ mA) and the no-model group ($M = 5.97$ mA), whereas these latter two groups did not differ from each other ($p > .10$). There were neither order nor trial effects.

Modeling effects were consistent whether judgments of physical intensity or subjective discomfort were required, with the biasing effects generally consistent across the range of judgmental categories. The tolerant-modeling impact was sufficiently substantial for those exposed to the tolerant model to not characterize as even painful those shocks deemed to be intolerable by subjects paired with an intolerant model or no model.

Tolerance levels were higher when attention was focused on personal discomfort ($M = 8.12$ mA), as contrasted with judgments emphasizing perceived physical intensity ($M = 7.26$ mA). The differential impact of the self-monitoring tasks indicated that the two sets of descriptors referred to discriminable states.

Questionnaire analyses of the severity of discomfort experienced when subjects were involved in either the ratings of physical intensity or affective discomfort indicated that when discomfort was being rated, the most intense shocks were described as less painful than when physical intensity was rated, $F(1, 24) = 7.37$, $p < .05$.

The study clearly demonstrated the substantial

effects of exposure to a tolerant model and that the social influence strategy equally affected characterizations of sensory and affective qualities. Additionally, instructional sets to attend to discomfort led to greater pain tolerance than instructions to describe the sensory quality of the experience, its physical intensity. Lower pain tolerance during intensity ratings was also characterized as more painful than the current intensities that provoked pain tolerance during the discomfort rating task.

A number of possible explanations could account for the superiority of the discomfort-rating task. Attending to personal discomfort may permit a more global and realistic appraisal of the experience. It also may have enhanced perception of the ability to control the experience, because subjective experiences tend to be seen as more amenable to volitional control than sensory experiences. Attending to affective components of experience may also have facilitated preparation for subsequent noxious experience. Restricting attention to the physical intensity scale may have left subjects unprepared for the severity of shocks at more intense levels.

Because clinical pain, in most instances, does not permit deliberate appraisal of low intensity levels, preparatory communications have been used effectively to manage stress reactions. Because of the problems involved in the choice of language to describe most probable reactions to noxious events, the present study indicates the need to instruct individuals to evaluate descriptions of others' experiences within the context of their own responses to noxious stimuli. Attention to different components of the pain experience itself may differentially affect qualities of the experience. Attending to some of the affective qualities of the experience would appear to be an important component of effective self-regulation.

Comparison of the Similarities and Differences in the Self-concepts of Male Alcoholics and Addicts

Jerome F. X. Carroll, M. Israel Klein, and Yoav Santo
Eagleville Hospital and Rehabilitation Center, Eagleville, Pennsylvania

This study compared self-concept scores from the Tennessee Self Concept Scale (TSCS) of 178 alcohol- and 156 drug-dependent male clients in an abstinent, therapeutic community. A multivariate analysis of the TSCS scores indicated that substance abuse, when age and race were statistically controlled, yielded only three significant results (True/False ratio; Psychosis; and Personality Disorder). These data were interpreted as indicating greater similarity than difference for the alcohol- and drug-dependent men regarding self-concept. The data also indicated the value of using a multivariate rather than a bivariate design in examining the relationships between substance abuse patterns and self-concept.

An increasing number of spokespersons within the substance-abuse field have advocated combined treatment, that is, treating alcoholics and drug addicts together in the same rehabilitation program (Carroll & Malloy, 1977). This proposal, however, raises a number of important questions, one of which is, to what extent are the personality dynamics of these two groups similar/dissimilar?

Even though research studies have shown that alcoholic or drug-dependent persons are low in self-esteem (e.g., Fitts, Arney, & Patton, 1973; Robinson, 1973), there has been little data published comparing the self-concepts of alcoholics and drug-dependent clients seeking treatment. We attempted to fill this gap by comparing the Tennessee Self Concept Scale (TSCS; Fitts, 1965) scores of alcoholic and drug-dependent men while statistically controlling for the effects of age and race.

The present study was undertaken at Eagleville Hospital and Rehabilitation Center, a residential therapeutic community whose abstinence treatment program serves a near-equal number of alcoholics and drug addicts. For a period of 6 consecutive months, all male clients with a diagnosis of either alcoholism or drug dependence who completed the TSCS as part of the standard group test battery at EHRC were included in this study.

Clients with a dual diagnosis of alcoholism and drug dependence were excluded from the study. So too were clients with severe reading problems, which prevented them from completing the TSCS.

No attempt was made to differentiate among alcoholics regarding their preference for beer, wine, or liquor, nor did we attempt to differentiate among the varieties of drug-dependent clients. Most of the drug-dependent clients had been referred for treatment due to heroin abuse, although they often had abused other drugs as well (e.g., marijuana and minor tranquilizers). Classification of clients as being either alcoholic or drug dependent was based solely on the extant system used by Eagleville Hospital and Rehabilitation Center's Medical Records Department for classifying newly admitted clients.

The sample consisted of 334 male clients; 178 had been diagnosed as alcoholics and 156 as addicts. With respect to race, 170 of the men were black and 164 were white. We divided our sample into four age groups (up to 23, 24-33, 34-44, 45 and older) as had been done in a previous study of EHRC clients by Barr, Ottenberg, and Rosen (Note 1).

A contingency analysis of the relationship between age and addiction indicated that these variables were not independent, $\chi^2(3) = 14.91$, $p < .005$. Not surprisingly, younger clients were significantly more likely to be drug addicts, and older clients were more likely to be alcoholics.

Similarly, a contingency analysis of the relationship between race and addiction indicated that these variables also were not independent, $\chi^2(1) = 11.41$, $p < .001$. Black clients were significantly

Requests for reprints and for an extended report of this study should be sent to J. F. X. Carroll, Director Psychological Services, Eagleville Hospital and Rehabilitation Center, Eagleville, Pennsylvania 19408.

more likely to be alcoholics, and whites were more likely to be addicts.

These results differ somewhat from reports received from the National Institute on Drug Abuse (NIDA) and the National Institute of Alcohol Abuse and Alcoholism (NIAAA). Reports from NIAAA indicate more white than black alcoholics are receiving treatment in federally funded programs, although we believe the extent of the alcohol abuse problem among blacks has been underestimated by these data. The distribution of races for drug abuse reported by NIDA correspond with the findings we have reported.

Having demonstrated that addiction was not independent of either age or race in our sample, a three-way analysis of variance was performed for each of the 29 TSCS scales to ascertain the unique contribution of addiction, age, and race, and their interaction effects on TSCS scores.

Addiction, as a main effect independent of race and age, yielded significant main effects for three TSCS scales, namely True/False ratio, $F(1, 319) = 3.51, p < .05$; Psychosis, $F(1, 319) = 4.07, p < .05$; and Personality Disorder, $F(1, 319) = 4.07, p < .05$. Alcoholics scored higher on the T/F ratio, indicating a more acquiescent response set, which we interpret to reflect a more passive and compliant coping style. The higher scores of the alcoholics on the Psychosis and Personality Disorder (empirical) scales indicated a greater degree of emotional distress, poorer reality contact, greater depression and emotional lability, greater mental confusion, higher levels of suspicion, and more personality weaknesses and vulnerabilities than that observed for addicts.

Race as a main effect, independent of substance of abuse and age, yielded two significant main effects, Total Conflict, $F(1, 319) = 5.14, p < .05$, and Personality Integration, $F(1, 319) = 4.00, p < .05$. Black males evidenced greater confusion, contradiction, and general conflict in self-perception than did white males. Black males also scored lower than white males on the Personality Integration scale.

There were no significant main effects due to age. This finding is in sharp contrast to that reported in a companion study (Carroll, Santo, & Klein, Note 2) using the Personality Research Form as a measure of normal personality needs. Apparently age exercises a greater influence when normal personality needs are measured and examined.

Concerning interaction effects, only two sig-

nificant results were observed. A significant interaction for race and age on the Behavior scale was obtained, $F(3, 319) = 2.98, p < .05$, with white males in the 24-33 age group scoring highest, and black males 23 years or younger and 45 years or older scoring lowest. We interpret the significant interaction effect as indicating that the greatest degree of guilt regarding behavior was borne by the two extreme age groups of blacks.

A significant interaction effect for race and addiction was observed on the Personality Integration scale $F(1, 319) = 4.94, p < .05$. In this instance, black alcoholics scored lowest, and white addicts scored highest.

While not minimizing the differences noted above, it is nonetheless important to note that nearly all of the scales that had been significant in various preliminary bivariate analyses (e.g., comparing race, age, or substance abuse and self-concept) ceased to be significant in the multivariate analysis. When race and age are controlled, therefore, alcohol- and drug-dependent men appear to be more similar than dissimilar with respect to their self-concepts.

Dimensions, Patterns, and Personality Correlates of Drug Abuse in an Offender Population

Terrill R. Holland
California Department of Corrections, Chino

Twelve drug abuse scores obtained from each of 215 prisoners were factor analyzed, resulting in two factors describing the lifetime degree of use of cannabis versus opiate types of drugs. Multiple discriminant analysis of Minnesota Multiphasic Personality Inventory (MMPI) profiles versus drug abuse patterns indicated a moderate, unidimensional relationship between these two sets of variables ($R_c = .38$, $p < .05$). The MMPI profiles of both groups of opiate users were configurally similar to, though less highly elevated than, those identified in previous research with narcotic addicts, suggesting certain differences between the present sample and drug abuse cases encountered in other settings.

Previous research on the average Minnesota Multiphasic Personality Inventory (MMPI) profile and the common profile types among drug-dependent individuals has focused primarily on narcotic addicts and has led to disagreement over questions of both the existence of personality patterns peculiar to addicts and the relative importance of psychopathic versus neurotic and/or schizoid components of addict profiles. However, drug abuse is a multidimensional phenomenon, and the classification of subjects based on multiple measurements reflecting types of drugs and parameters of use would be expected to yield more accurate descriptions of drug abuse patterns and correlates than has been possible by comparing the profiles of extreme groups of individuals designated as either addicts or non-addicts.

In light of the foregoing considerations, the drug abuse histories of 215 prisoners undergoing felony presentence evaluation at the California Institution for Men, Chino, were quantified by scoring each of three major classes of drugs: opiates, nonopiate "hard" drugs, and cannabis)

Grateful acknowledgment is given to Hung Tran for data processing assistance and to Kathleen McKay for clerical support.

Although conducted under the auspices of the Department of Corrections, the opinions expressed here are the views of the author and do not necessarily reflect the official position of the California Department of Corrections or the Health and Welfare Agency.

for four parameters of use (frequency of use, method of administration, age at first exposure, and years of use) using a modification of the scale described by Gunderson, Russell, and Nail (1973). The 12 scores obtained in this fashion were standardized and subjected to a principal components analysis with varimax rotation, resulting in two factors with eigenvalues greater than one. As shown in Table 1, cannabis parameters load most highly on Factor 1, opiate parameters load on Factor 2, and nonopiate hard drug parameters load on both factors, indicating that a two-dimensional model of drug abuse is appropriate for the present subjects and method of measurement. Since parameters of use are not statistically distinct from each other, and since the use of nonopiate hard drugs is not distinct from the use of cannabis and opiates, the 12 drug scores reduce to two underlying dimensions describing the lifetime degree of use of cannabis versus opiate types of drugs.

Calculating factor scores for individuals and dividing the distributions of these scores at the median resulted in four groups defined by levels and combinations of the two drug abuse dimensions. The groups and their associated sample sizes and MMPI Welsh codes are as follows: low cannabis-low opiate ($n = 79$) = $49 - 5268371 / KFL$; high cannabis-low opiate ($n = 50$) = $49 - 8562731 / KFL$; low cannabis-high opiate ($n = 24$) = $428967 - 531 / F - KL$; and high cannabis-high opiate ($n = 62$) = $49578 - 2631 / FKL$. Multiple discriminant analysis of these profiles yielded a single significant dimension of group difference ($R_c = .38$; $\Lambda = .78$), $\chi^2(36) = 51.31$, $p < .05$, the composi-

Table 1

Varimax Rotated Factor Loadings for Drug Abuse Scores

Score	Factor 1	Factor 2
Opiate rate	.241	.934
Opiate method	.250	.935
Opiate age	.241	.889
Opiate duration	.195	.919
Hard drug rate	.680	.594
Hard drug method	.664	.641
Hard drug age	.718	.513
Hard drug duration	.659	.600
Cannabis rate	.875	.200
Cannabis method	.905	.158
Cannabis age	.864	.156
Cannabis duration	.883	.280
Eigenvalue	8.208	1.910
Proportion of variance	.684	.159

tion of which may be interpreted on the basis of "structure coefficients," that is, bivariate correlations between the total discriminant score and each of the original variables (Cooley & Lohnes, 1971). In this respect, the groups are maximally discriminated along a dimension that is correlated .30 or greater with Scales $F(r = -.39)$, $D(r = -.32)$, $Pd(r = -.73)$, $Pa(r = -.30)$, $Pt(r = -.48)$, and $Sc(r = -.36)$, with selective opiate users manifesting the highest score in each instance. One-way univariate analyses of variance resulted in statistically significant F ratios for D ($p < .05$), Pd ($p < .001$), and Pt ($p < .05$).

The findings indicate a moderate, unidimensional relationship between pattern of drug abuse and MMPI performance. To the extent that these two sets of variables are related to each other, nondrug users and selective cannabis users exhibit the least pronounced personality liabilities, whereas selective and nonselective opiate users manifest the most conspicuous deficiencies. Further, although all four group profiles are suggestive, to a greater or lesser degree, of social nonconformity, the selective opiate group is characterized by mild, though noteworthy, additional elements of subjective distress and disturbed thinking.

The configurations of the MMPI profiles of

both of the present groups of opiate users are similar to the major profile types identified through cluster analysis by Berzins, Ross, English, and Haley (1974) among narcotic addicts, thus providing additional support for the hypothesis that opiate dependence occurs within more than one personality context. Nonetheless, the present profile elevations are considerably lower than those obtained in both the Berzins et al. study and in most previous research on the relationship between drug abuse and MMPI performance. These differences might be attributed partially to the profile-suppressing variables of detoxification, nonvolunteer status, and incarceration in a relatively protected environment. However, this trend is also consistent with the tendency of presentence cases of the type studied to exhibit a generally lesser degree of psychopathology on the MMPI than most other groups of incarcerated offenders (Holland & Holt, 1975). Factors probably responsible for this phenomenon are the motivation of the subjects to present themselves in a favorable light to their evaluators, optimism resulting from the possibility of returning home on probation in the foreseeable future, and an element of selectivity in which many offenders who are clearly emotionally disturbed are often incorrectly perceived by the courts as being dangerous and therefore are given lengthy sentences without first being referred for presentence evaluation through the state prison system.

MMPI Evaluation of 5-Year Methadone Treatment Status

Gennaro Ottomanelli, Peter Wilson, and Richard Whyte
Department of Psychiatry, Downstate Medical Center
State University of New York, Brooklyn

Treatment outcome over a 5-year period was evaluated for 148 first admissions to a methadone treatment program. Eleven patients (7%) were successful treatment completions, 16 patients (11%) transferred to other methadone programs, 38 patients (26%) remained in continuous treatment, and 83 patients (56%) were unsuccessful treatment terminations. Discriminant analysis using the Minnesota Multiphasic Personality Inventory (MMPI) suggested that the more stable patients at admission had the best treatment outcome. For the patients in continuous treatment, MMPIs administered at 6-week, 6-month, and 5-year intervals indicated that this group of patients did not change on the personality dimension.

The questions formulated for research were (a) Is the Minnesota Multiphasic Personality Inventory (MMPI) useful in predicting long-term treatment outcome for methadone patients? Also, does the MMPI present different group characteristics representative of different treatment outcomes? and (b) Given a group of methadone patients in long-term treatment, does the MMPI demonstrate change over time on the personality dimension?

The sample consisted of 148 narcotic addicts admitted to a methadone clinic at the Kings County Addictive Disease Hospital, Brooklyn, New York, during 1971. The sample represented voluntary first admissions to the methadone clinic. The criteria for program admission were 2 or more years of admitted drug use, age over 20 years, and absence of overt psychosis (determined by psychiatric evaluations). The sample consisted of 110 (74%) males and 38 (26%) females with a mean age of 27.14 years ($SD = 6.26$); 73 (49%) were white, 43 (29%) were black, and 32 (22%) were Hispanic. The sample had a mean of 2.19 months ($SD = 3.51$) of employment in the 1 year prior to admission, a mean of 3.11 arrests ($SD = 4.02$) prior to admission, and a mean length of drug use of 94.07 months ($SD = 55.8$ months).

The MMPI and a questionnaire eliciting demographic information were administered

within 6 weeks after admission. Another questionnaire eliciting employment and arrest information, housing stability, current sources of income, and methadone-related attitudes supplemented the MMPI administration at the 5-year follow-up. MMPI profiles were classified as invalid on the basis of an F score ≥ 22 .

Treatment outcome over a 5-year period for the group of 148 patients showed that 11 patients (7%) completed treatment, 38 patients (26%) were in continuous treatment for 5 years, 83 patients (56%) were unsuccessful treatment terminations (patients discharged for an assortment of administrative and disciplinary reasons), and 16 patients (11%) had transferred to other methadone programs. Of the 148 patients admitted to the study, 38 patients did not cooperate with the MMPI testing. This patient group consisted of 29 males (76%) and 9 females (24%); 14 patients (37%) were white, 15 (39%) were black, and 9 (24%) were Hispanic. Five-year treatment outcome for this group showed that 3 patients (8%) were treatment completions, 4 patients (10%) were in continuous treatment for 5 years, 29 patients (76%) were unsuccessful treatment terminations, and 2 patients (5%) transferred to other programs.

The remaining 110 patients completed the MMPI within 6 weeks after admission. Five-year treatment outcome for this group showed that 8 patients (7%) were treatment completions, 34 patients (31%) were in continuous treatment for 5 years, 54 patients (49%) were unsuccessful treatment terminations, and 14 patients (13%) transferred to other programs. The demographics of the 110 MMPI patients

Requests for reprints and for an extended report of this study should be sent to Gennaro Ottomanelli, Department of Psychiatry, Downstate Medical Center, State University of New York, Box 9, Code 24, 450 Clarkson Avenue, Brooklyn, New York 11203.

classified according to treatment outcome are as follows: (a) The 8 patients in the treatment-completed group consisted of 7 males (88%) and 1 female (12%); 3 were white (37%), 3 were black (37%), and 2 were Hispanic (25%). (b) The in-treatment group consisted of 25 males (74%) and 9 females (26%); 20 were white (59%), 5 were black (15%), and 9 were Hispanic (26%). (c) The unsuccessful treatment group consisted of 41 males (76%) and 13 females (24%); 27 were white (50%), 15 were black (28%), and 12 were Hispanic (22%). (d) The transferred group contained 14 patients, 7 males (50%) and 7 females (50%); 9 were white (64%) and 5 were black (36%).

Discriminant analysis was used to evaluate treatment outcome based on the MMPIs administered in the 6th week after admission. The groups were sorted on the basis of 5-year treatment outcome, that is, treatment completed (successful treatment effort), currently in treatment, and unsuccessful treatment terminations. One patient, in each of the treatment completed, active, and unsuccessful treatment groups was eliminated from the discriminant analysis because of invalid MMPIs ($F \geq 22$). A chi-square analysis compared the accuracy of the classification matrix of the discriminant functions with the expected frequencies based on chance and was found to be statistically significant, $\chi^2(4) = 27.83$, $p < .01$.

Comparison of the means of the MMPI scales for the patients grouped on the basis of treatment outcome showed that the patients in the successful treatment group ($n = 7$) had their highest mean T scores on the Pd (70.00) and Ma (66.29) scales, whereas the remaining eight MMPI clinical scales ranged from a mean of 64 (D) to a mean of 50.14 (Si). For the patients who remained in treatment ($n = 33$), the highest mean T scores were obtained on the D (71.48) and Pd (74.21) scales, and the remaining eight MMPI clinical scales ranged from a mean of 66.03 (Ma) to a mean of 57.36 (Si). For the patients in the unsuccessful treatment group ($n = 53$), the highest mean T scores were obtained on the Pd (72.34) and Ma (70.85) scales, and the remaining eight MMPI clinical scales ranged from a mean of 68.07 (Sc) to 54.30 (Si). Generally, the scales satisfied clinical expectations on two counts: (a) The patients with the best treatment outcome, that is, the treatment completed group, were the most stable at the time of admission, since this group had the lowest mean T score on 8 of 10 clinical scales of the MMPI; and (b) there was a linear trend (i.e., the rela-

tionship approaches a straight line) for the three groups on the F , Pa , Pt , and Sc scales that rank patients on emotional traits, leading to a greater probability of acting out and concomitant greater probability of unsuccessful treatment.

Although attempts were made to retest the 34-patient MMPI in-treatment group, only 24 patients in this group provided valid 6-week and 5-year MMPIs; within this subgroup were 13 patients who completed the MMPI at 6-week, 6-month, and 5-year intervals. Although the 24-patient group showed increased scores on K , Hs , D , Hy , Pd , Mf , Pa , Pt , and Sc from the 6-week to the 5-year testing interval, Hotelling's T^2 for a one-sample test-retest design using 12 scales (K was excluded from the analysis) was not statistically significant, $F(12, 12) = 2.06$, $p > .05$.

Since the 13-patient subgroup had been tested on three occasions in the follow-up period, an additional analysis was conducted on these three test occasions. The comparison of 12 MMPI scores (the K scale was excluded) for 6 weeks and 6 months was not statistically significant; Hotelling's T^2 for one sample, $F(12, 1) = 47.82$. Likewise the comparison of the 12 MMPI scores for the 6-month and 5-year intervals was not statistically significant; Hotelling's T^2 for one sample, $F(12, 1) = 2.24$.

Aside from the patients who transferred to other institutions, the MMPIs of the three groups appear to be in accord with clinical expectations; that is, the most stable group at admission consisted of those patients who successfully completed treatment. Those patients who remained in treatment had their highest MMPI elevations on the D and Pd scales. For this group the pharmacology of methadone as a potent analgesic may have been an influential factor. The unsuccessful treatment group had their highest MMPI elevations on the Pd , Sc , and Ma scales, with the accompanying higher probability of acting out and higher probability of unsuccessful treatment termination.

The follow-up of the 24-patient group in continuous treatment for the 5-year period did not demonstrate substantive gains on the personality dimensions measured by the MMPI. When one considers the analysis of the MMPIs of the 24-patient group and the analysis of the 13-patient subgroup, it appears that the patients remained unchanged on the personality dimensions at 6-week, 6-month, and 5-year intervals. Although the results of the present 148-patient study are subject to the limitations imposed by a one-

sample design with patients cooperating on a voluntary basis, the findings of the present study suggest that methadone stabilization is most effective for the small proportion of patients with personality and social strengths. Methadone patients who are treatment manageable but lacking in personality and social strengths remain in treatment to preserve marginal social function-

ing, with minimal improvement resulting from long-term stabilization. The marginal social functioning of this group could deteriorate if treatment efforts are terminated. The largest group of patients studied were treatment unmanageable and unsuccessful treatment terminations.

Stimulus-Seeking Behavior in Three Delinquent Personality Types

David A. Shostak
University of Virginia

Curtis W. McIntyre
Southern Methodist University

This study examined stimulus-seeking behavior in three delinquent personality types (psychopathic, neurotic, and socialized) drawn from three populations (juvenile delinquent, young adult offenders, and college). Results from a kinesthetic aftereffect task and the Sensation Seeking Scale indicate only limited evidence of pathological stimulus seeking by the psychopathic delinquent personality type. We suggest that this limited evidence results from the incarceration experiences of the young adult offenders.

Three delinquent personality types (unsocialized psychopathic, disturbed neurotic, and socialized delinquent) have been described by Quay (1965). Moreover, Quay has suggested that the behavior of the unsocialized psychopath results from pathological stimulus seeking.

More recently, individual differences in stimulus-seeking behavior have been investigated by two personality researchers, Petrie (1967) and Zuckerman (1971). Petrie has shown that individuals differ in their tendency to reduce or to augment stimulation received during a kinesthetic aftereffect task (KAE). Reducers subjectively diminish their sensory input and seek higher levels of stimulation. Augmenters subjectively increase their sensory input and avoid higher levels of stimulation. Zuckerman has shown that individuals differ in the optimal level of stimulation they seek as measured by his Sensation Seeking Scale (SSS).

In the present study, Quay's suggestion that the unsocialized psychopath is a pathological stimulus seeker was tested by administering the KAE and SSS to all three delinquent personality types. The general expectation was that unsocialized psychopaths would be reducers on the KAE and high scorers on the SSS.

Three male populations were used: juvenile offenders (M age = 15 years 2 months), young adult offenders (M age = 20 years 6 months), and college students (M age = 19 years). Ten subjects of each delinquent personality type were selected within each population using the Quay and Peterson Personal Opinion Questionnaire. Following selection, each subject took the KAE and SSS.

Requests for reprints and for an extended report of this study should be sent to Curtis W. McIntyre, Department of Psychology, Southern Methodist University, Dallas, Texas 75275.

Separate one-way analyses of variance were applied to each population to assess stimulus-seeking differences between the three delinquent personality types. With respect to the KAE, the only significant difference was found for the young adult offenders, $F(2, 36) = 3.39, p < .05$. On this task the unsocialized psychopaths reduced most; that is, they sought higher levels of sensory input. A general tendency to reduce was observed for both the juvenile and young adult offender populations.

With respect to the SSS, no differences between the three delinquent personality types were found for any of the three populations tested. Evidently, sensation seeking (as measured by the SSS) was uniform across all three diagnostic categories. In addition, correlations between the KAE and each subscale of the SSS failed to reach significance for any of the personality types and populations. Evidently, the stimulus-seeking behaviors assessed by these measures were independent.

In conclusion, only limited evidence of pathological stimulus seeking by Quay's psychopathic delinquent personality type was found. Moreover, we suggest that this limited evidence may not be etiological in nature but may result from the longer incarceration (or isolation) experiences of the young adult offenders.

Validity Generalization of the WISC-R Factor Structure with 10½-Year-Old Children

David A. Shiek and John E. Miller
Western Kentucky University

The purpose of this study was to investigate the robustness of the Wechsler Intelligence Scale for Children-Revised (WISC-R) factor structure. The generalization sample was composed of 126 10½-year-old children of which 62 were male and 64 were female. A principal-components method of factor analysis yielded three reliable factors. Comparisons of the loadings obtained with the generalization sample and the 10½-year-old national standardization sample suggest a high degree of similarity in composition, magnitude, and pattern. The findings highly support the robustness of the WISC-R's factor structure across divergent 10½-year-old samples.

The purpose of this study was to investigate the robustness of the factor structure of the Wechsler Intelligence Scale for Children-Revised (WISC-R). The factor analysis of the standardization data (Kaufman, 1975) yielded three stable factors: Verbal Comprehension, Perceptual Organization, and Freedom from Distractibility. The present sample was composed of 126 children with a mean age of 10.6 years from lower to lower-middle-class homes in the central south-eastern United States. The sample was composed of 62 males and 64 females of which 87 were white and 39 were black. A preliminary analysis indicated two basic differences between this sample and the standardization sample: The Verbal, Performance, and Full Scale IQs were significantly lower, and the variances on the Performance and Full Scale variables were significantly restricted.

The primary analysis consisted of a principal-components method of factor analysis with squared multiple correlations in the diagonals and a varimax rotation procedure. This procedure yielded three reliable factors with eigenvalues greater than 1.0. The first factor (Verbal Comprehension) consisted of Information, Vocabulary, Similarities, and Comprehension. The second factor (Perceptual Organization) was composed of Block Design, Object Assembly, Picture Completion, Mazes, and Picture Arrangement. The

third factor (Freedom from Distractibility) included Coding, Arithmetic, and Digit Span. Comparisons of the factor structure obtained with the generalization sample (this study) and Kaufman's (1975) 10½-year-old national standardization group were made. Visual comparisons of the loadings obtained on the two analyses suggested a high degree of similarity in the loadings. Vector comparisons yielded an intraclass coefficient of .89, indicating a high degree of similarity in pattern and magnitude in the factor loadings. Matrix comparisons indicated that the three factors were similarly delineated in both analyses.

When compared to Kaufman's (1975) findings and conclusions, the factor structure obtained with the generalization sample was highly consistent. Only insignificant variations in the two solutions were present, and the factor structure of the WISC-R appeared quite stable across the two relatively divergent 10½-year-old samples. The conclusions highly supported the robustness of the WISC-R's factor structure and Wechsler's original proposition that his scales assess verbal, performance, and nonintellectual functions. The existence of such a stable factor structure suggests the possibility of exploration as to the clinical usefulness of factor scores in differential diagnosis and prediction.

Comparison of Self-administered and Examiner-administered Depression Adjective Check Lists

Bernard Lubin
University of Missouri at Kansas City

Joseph G. Marone
Norwich Hospital
Norwich, Connecticut

Ronald G. Nathan
University of Houston and
Texas Research Institute of Mental Sciences, Houston

Self-administered and examiner-administered Depression Adjective Check Lists were compared. One half of each equivalent form A, B, C, D was administered in the standard manner and one half was read by the examiner to 64 male and 64 female psychiatric inpatients. The Wechsler Adult Intelligence Scale Vocabulary subtest was administered at the same time. A repeated measures analysis of variance revealed no significant effects for vocabulary (median split), sex, or method of administration. The significant main effect of lists seems best understood as a chance finding. The results support the use of the examiner-administered method in cases of functional illiteracy.

The standard method of administration of a number of self-administered personality measures used in research and in clinical practice is not feasible in the case of persons who are functionally illiterate. The possible effects of substituting examiner administration for self-administration is an important but relatively unexplored question. Earlier work comparing the two methods of administering the Rotter Incomplete Sentences Blank (Flynn, 1974) and the Minnesota Multiphasic Personality Inventory (Reese, Webb, & Foulks, 1968) found no significant differences. Unfortunately, these instruments do not have alternate forms, and the findings might be the result of practice effect. In addition, these findings were established with "trait" measures; they might not generalize to "state" measures.

The Depression Adjective Check Lists (DACL; Lubin, 1967) were designed as brief, self-administered measures of transient depressive mood. Their alternate forms (Lubin, 1967; Lubin, Dupre, & Lubin, 1967) make them useful in comparing administration methods.

Sixty-four male and 64 female psychiatric inpatients of a large state hospital were individually

administered Set 1 of the DACL (Forms A, B, C, and D) in random order. Each form was divided so that one column was administered verbally by the experimenter and one column was self-administered (written) by the subject. The order of columns was counterbalanced. The Vocabulary subtest of the Wechsler Adult Intelligence Scale was then administered to study the effect of verbal fluency on DACL scores. A median split of the scaled scores was used to analyze the effect of this factor.

A repeated measures analysis of variance revealed a significant main effect of lists, $F(3, 372) = 23.09$, $p < .001$, but no significant effects of vocabulary, sex, or method of administration on the depression scores. The significant main effect of lists was not consistent with earlier findings (Lubin, 1967; Lubin et al., 1967). It seems best understood as a chance finding and thus uninterpretable.

There was no significant difference between self-administered ($M = 5.80$, $SD = 4.23$) and examiner-administered ($M = 5.53$, $SD = 4.20$) depression scores. In fact, the self-administered scores averaged only about $\frac{1}{2}$ point higher on the standard DACL (range = 0-34) than the examiner-administered score. The trend of $F(1, 124) = 3.42$, $p < .07$, should be interpreted within the perspective of the high intercorrelations among lists across administrations (mean $r = .85$, $n = 12$).

These results strongly suggest that the two methods of administering the DACL are similar,

We wish to acknowledge the assistance of Bob Paver, Jim Millham, Linda Peterson, and Daniel Sheer.

Early Childhood Autism and Structural Therapy: Outcome After 3 Years

Alan J. Ward

Henry Horner Children's Center, Chicago, Illinois

The effect of 3 years of structural therapy on 21 inpatient cases of early childhood autism (ECA) is examined. Treatment resulted in the discharge of 12 patients. Details of treatment procedure, therapeutic progress, and their effects on diagnostic and prognostic conceptualizations are presented. Comparisons are made among previous reports of attempted treatment of ECA, as well as the results of two other treatment units in the same setting. Results support the hypothesis that the high stimulation, physically intrusive, gamelike, novelty filled, and developmentally oriented treatment approach of structural therapy is capable of producing a significant improvement in cases of ECA.

This article is a preliminary report on the outcome of the application of structural therapy to the residential treatment of early childhood autism. The term *early childhood autism* (ECA) is used to include both the classically defined rare cases of early infantile autism (EIA), as well as the much more common cases of organic autism and the variously handicapped and/or disturbed children who are mistakenly labeled as suffering from EIA.

The treatment of EIA is a topic that has usually aroused great feelings of futility.

Examination of outcome data reported by both Bettelheim (1967) and by Eisenberg (1956) revealed strongly contrasting findings. Eisenberg's follow-up evaluation was divided into the three categories of poor, fair, or good outcome.

Bettelheim has reported outcome figures on a group of 40 "autistic" children and has used the categories devised by Eisenberg. A good outcome was reported for 17 children (42%); a fair outcome, for 15 children (38%); and a poor outcome, for only 8 patients (20%). These outcome figures are in marked contrast to those reported by Eisenberg of 5% for a good outcome, 22% for a fair outcome, and 73% for a poor outcome.

A new therapeutic approach labeled *structural therapy* (Ward, 1970) was used in the development of a treatment program for EIA children.

Evaluation of the 21 original children in this

program revealed only 4 children who met the research definition of EIA, which was (a) lack of the development of object relations from birth; (b) lack of the use of speech for communication; (c) maintenance of sameness via stereotypic behavior with a rage or withdrawal reaction on interruption, and (d) no major neurological dysfunction. The behavioral characteristic of "lack of affective response" is one that was evaluated and agreed on by both me and the co-director of the program, H. Allen Handford. This evaluation was based on clinical interview, play observation, family interview, and review of clinical referral material that included social history, psychological evaluation, psychiatric evaluation, and pediatric neurological evaluation. The other children fell into the diagnostic categories of childhood schizophrenia (5) primary retardation (7), secondary retardation (3), and developmental retardation associated with diffuse brain damage (2). However, all of these children were found to display the behavioral characteristics of a "lack of affective response," whereas children from all five of the above diagnostic categories were found to display the characteristics of "lack of object relationships," "lack of the use of speech for communication," and of having come from an "unstimulating mother/infant relationship." The 4 EIA cases were distinguished from the other disturbed children by their combination of (a) lack of neurological dysfunction and their (b) maintenance of sameness via stereotypic behavior.

The total research unit was organized according to the precepts of structural therapy. The milieu emphasized spontaneous physical and verbal stimulation applied to the children in a playful and gamelike fashion. The goal of this approach

Requests for reprints and for an extended report of this study should be sent to Alan J. Ward, Henry Horner Children's Center, 6500 West Irving Park Road, Chicago, Illinois 60634.

was to increase the amount of varied and novel stimulation received by these children and to use this increased stimulation to make them more aware of their external environment and to help them to progress from their positions of early developmental fixation. The physical stimulation was used to develop body image and bodily awareness and to help provide the body ego, which appears to be necessary for the development of higher ego functions. Twelve of the 21 children were seen in individual therapy on a twice weekly basis, although often the children were seen on an informal basis five times a week. Selected children were seen for sessions in speech therapy on a twice weekly basis for periods ranging from 3 months to 2 years.

Families were contacted on a weekly basis by the social workers. Group counseling was provided on a biweekly basis for all of the parents, and the majority of them had a weekly day visit, overnight visit, or weekend visit with their child.

The basic goal of this structural therapy treatment program has not been "cure" but development. EIA and ECA are viewed as severe developmental disorders of the same kind as are often observed with the rubella child, the blind child, or the deaf child. The basic etiology is considered to be rooted in a deficit of novel and varied stimulation for multiple reasons.

This treatment program attempted to help these children to progress to the point where they achieved the goals of (a) relationships with people; (b) self-care such as toilet training, feeding, and dressing; (c) communication of simple needs in a consistent manner; and (d) the capacity to follow simple directions. The achievement of these goals revealed a child who was still functioning below age-appropriate level in regard to cognitive and affective behavior. The child was now at a point in development in which more conventional play therapy, speech therapy, and/or special education could be used. It was felt that these children should be viewed as being in the midst of their therapeutic course at the time of discharge. They were discharged at this point because the institution was no longer able to provide the needed therapeutic level of stimulation. Those children who were discharged to their homes in the community seemed appropriate for placement in Eisenberg's category of fair outcome. Each child was used as his or her own control in this research, but some comparisons will also be drawn with two other treatment units, in the same setting, that have attempted to work with autistic children (ECA).

The application of 3 years of structural therapy

to the original group of 21 cases of ECA resulted in the discharge to homes in the community of 12 of the original 21 children (57%). These children were placed in normal nursery schools, special classes for the retarded or the emotionally disturbed in public schools and private schools, and sheltered workshops run by the local association for retarded children. The families were referred to the appropriate agencies for continued counseling.

The experimental unit was Unit A, which had a population of boys and girls with a mean age of 8.9 years and 10.2 years, respectively, at admission and whose mean length of prior hospitalization was 1.08 years and 1.92 years. Inspection of comparable data on Comparison Units B and C revealed little difference as to mean age but a great difference as to length of prior hospitalization. These data suggest that the children on Unit A were more severely disturbed than those on Unit B or Unit C. The boys on Unit B had a mean age of 7.2 years on admission and a mean length of prior hospitalization of 6.5 months, whereas the girls on Unit C had a mean age of 8.9 years on admission and a mean length of prior hospitalization of 5.9 months.

Between September 1966 and September 1969, Unit A discharged 12 cases of ECA to home in the community, whereas Unit B discharged 2 boys and Unit C discharged 5 girls. A comparison of the outcome figures of Eisenberg and Bettelheim, vis-à-vis Units A, B, and C, revealed that Unit A exceeded both Eisenberg's and Bettelheim's results in regard to the percentage of children who achieved a fair outcome. Unit C's outcome rate of 25% approximated the outcome rate reported by Eisenberg (22%), but Unit B's outcome figure of 9% fell markedly below that. A classical, psychodynamically oriented psychotherapy and play therapy treatment was used in both Units B and C.

The outcome figures of this preliminary study appear to support the hypothesis that structural therapy is capable of producing significant therapeutic change in children classified as having ECA.

Coital Position and Sex Roles: Responses to Cross-sex Behavior in Bed

Elizabeth Rice Allgeier
State University of New York, Fredonia

Arthur F. Fogel
Eastern Michigan University

The impact of changes in sex role norms regarding heterosexual interaction was explored by varying both the coital position used by a couple in stimulus slides and the extent to which observers identified with stereotypic sex role norms. Females were more negative toward the couple having intercourse in the woman-above position than they were toward the couple in the woman-below position. Observers' degree of sex typing was unrelated to their reactions to the woman-above couple, suggesting that gender may still be more important than sex typing in determining responses to roles in the context of heterosexual interaction.

Some physicians have claimed that female liberation (and the increased demand for male performance) is the primary cause of an increase in male impotence (Liddick, 1972). On the basis of interviews with 50 men, however, Bry (1975) concluded that men prefer sexually aggressive women. Hunt (1974) suggested that the norm of male dominance and female submissiveness during intercourse has been changing, but to date, we have no experimental evidence to indicate the average person's reaction to female assertiveness in bed, nor do we know attitudes toward the male when he assumes the more submissive position.

Thus, one purpose of the present research was to explore male and female reactions to variations in coital positions relevant to sex role norms. Aside from giving birth, there is probably no other arena in which traditional gender role differences have more importance to us than in our sexual interaction. Thus, it was hypothesized that subjects would make more negative attributions about a couple engaging in women-above intercourse than about the same couple engaging in women-below intercourse.

This research was part of a doctoral dissertation submitted by the first author to Purdue University and was supported by National Science Foundation Grant SOC 74-15254 to Donn Byrne.

The authors gratefully acknowledge the helpful comments of Rick Allgeier, Donn Byrne, Rick Kimball, Don Lehr, Dave Przybyla, and Winnie Shepard on an earlier draft.

Requests for reprints and for an extended report of this study should be sent to Elizabeth Rice Allgeier, Department of Psychology, State University of New York, Fredonia, New York 14036.

The second purpose of the research was to see if observers' degree of sex typing would influence their responses to traditional versus nontraditional coital positions. Bem (1976) has demonstrated that androgynous persons (those who give equally high endorsement to masculine and feminine traits as self-descriptive) are more willing to engage in cross-sex behavior, and are more comfortable while doing so, than are sex-typed persons. Accordingly, it was hypothesized that sex-typed persons would respond more negatively to the couple in the women-above position than would androgynous persons.

Subjects were 119 unmarried, introductory psychology students at Eastern Michigan University who volunteered to participate in a study entitled *Responses to Erotica*. After students had completed a demographic questionnaire and the Bem (1974) Sex-Role Inventory, six slides of a couple engaged in intercourse were projected onto a large movie screen for 1 minute each. All students saw three "neutral" slides of the nude couple lying side by side mutually engaged in foreplay. In addition, half of the students saw three slides of the couple having intercourse in the woman-above coital position, and the other half of the students saw three slides of the couple in the woman-below coital position. Students were then instructed to complete a person perception task by checking a scale position along each of nine 7-point bipolar scales that best reflected their impressions of the woman (man) in the slides with respect to the dimensions of adjustment, cleanliness, respectability, morality, femininity (masculinity), goodness, sophistication, desirability as a wife (husband), and desirability as a mother (father).

Results of the $2 \times 2 \times 2$ (Coital Position \times Students' Gender \times Sex Typing) unweighted means analyses of variance indicated consistent interactions between subjects' gender and the coital position on ratings of the woman's cleanliness, $F(1, 111) = 5.68$, $p < .01$; respectability, $F(1, 111) = 7.96$, $p < .01$; morality, $F(1, 111) = 8.79$, $p < .005$; goodness, $F(1, 111) = 7.45$, $p < .01$; desirability as a wife, $F(1, 111) = 5.39$, $p < .05$; and desirability as a mother, $F(1, 111) = 5.92$, $p < .05$. Gender \times Coital Position interactions were also obtained on ratings of the man's cleanliness, $F(1, 111) = 5.61$, $p < .05$; respectability, $F(1, 111) = 5.74$, $p < .05$; morality, $F(1, 111) = 6.80$, $p < .01$; and masculinity, $F(1, 111) = 7.10$, $p < .01$.

Internal comparisons revealed that females consistently rated the couple in the woman-above position significantly more negatively than they did the couple in the woman-below position. Specifically, females rated the woman as dirtier, less respectable, less moral, less good, less desirable as a wife, and less desirable as a mother when she was on top than when she was beneath the man during intercourse.

Females also rated the man as dirtier, less respectable, less moral, and less masculine when he was in the woman-above position than when he was in the woman-below position. Males, on the other hand, tended to respond more positively to the couple in the woman-above position than in the woman-below position; however, the differences were not significant. Thus, the hypothesis regarding responses to variations in coital position was supported with respect to the responses of females and rejected with respect to the responses of males. No differences emerged as a function of the extent of students' sex typing, so the second hypothesis was rejected.

The finding that females (but not males) discriminated against the woman-above couple is particularly interesting in light of Masters and Johnson's (1966) finding that the female coital response develops more rapidly and with greater intensity in the woman-above position than in any other. The design of the present study does not allow us to determine why females responded as they did to the woman-above couple, and further research should be conducted to determine the extent to which their bias is a result of the belief that males find female assertiveness in bed threatening or unattractive. If this were the case, and if further research replicates the finding that males do not discriminate in their evaluations of a couple based on coital position, such informa-

tion might be very useful to the therapist working with nonorgasmic women who inhibit their own initiative due to fear that they will displease or threaten their mates.

The failure of students' sex typing to interact with coital position is in apparent contradiction to the findings of Bem (1976) that the extent of sex typing influences such diverse behaviors as nurturance, independence of judgment, and willingness to engage in cross-sex behavior. On the other hand, none of her designs have studied the context of heterosexual activity, and it may be that the influence of variations in sex typing does not yet extend to relations between the sexes. Support for this possibility is provided by Zeldow (1976), who found no relationship between sex typing and scores on the Attitudes Toward Women Scale (Spence & Helmreich, 1972). A number of the items in this scale deal with sexual relations, and this may be the area in which women feel most reluctant to abandon the feminine norms with which they were raised. Further research should be aimed at determining if sex typing does influence attitudes and behavior during heterosexual interaction in less explicitly sexual contexts (e.g., initiation of dates, sharing cost of dates, etc.) or if the effect of sex typing is negligible in any context involving male-female interaction.

Variations in a Construct: Quantitative and Qualitative Differences in Children's Locus of Control

Philip C. Kendall
University of Minnesota

A. J. Finch, Jr.

Richmond

Verda L. Little and Bernard M. Chirico
Virginia Commonwealth University

Thomas H. Ollendick
Indiana State University

The present study examined differences in locus of control scores and factor patterns among normal and nonnormal groups and male and female normals using the Nowicki-Strickland Locus of Control Scale for Children. Multidimensionality of the locus of control construct in children was supported by separate factor analyses of emotionally disturbed, delinquent, and elementary public school children. Qualitative differences in factor patterns between normals and nonnormals raised questions about interpreting inventory scores as reflecting the same construct for differing subject groups.

Locus of control refers to whether people perceive positive and negative outcomes of events as being contingent on their own behavior (internal) or the result of luck, fate, or powerful others (external). Considerable research has been conducted to investigate locus of control as a generalized expectancy (see Lefcourt, 1972), and factor analytic studies with adults support a multidimensional conceptualization of the locus of control construct (Levenson, 1973).

The present studies were designed to examine locus of control as it operates in normal (N1) and emotionally disturbed (ED) children and in juvenile delinquents (JD). Data from a second and larger group of normals (N2) were collected to allow an examination of sex differences.

The N1 group (M age = 10.9) contained 64 male and 43 female children. The N2 sample included 145 males (M age = 10.3) and 125 females (M age = 10). Although obtained from different systems, both normal groups were from suburban public schools in middle-class neighborhoods. The ED group contained 189 hospitalized children (M age = 11.1; 151 males, 38 females) for whom psychiatric screening indicated average

or above intellectual potential and a wide range of diagnoses. Although chronologically older (M age = 15.3), the JD group of 185 children (144 males, 41 females; M IQ of 69 children = 83.5) had a mean reading level (4.5) and mental age (11.3) comparable to children in the other groups.

All children completed the Nowicki-Strickland Locus of Control Scale for Children (Nowicki & Strickland, 1973) with individual attention provided when necessary to insure understanding. This scale was selected over other measures, because it has been found to be unrelated to social desirability or intelligence test scores and because it was thought to be the most reliable measure of generalized locus of control appropriate for children of a variety of ages. Scales were scored in the external direction.

The respective means and standard deviations for the N1, ED, and JD groups were 14.63, 5.59; 17.54, 4.41; and 15.60, 5.17.¹ Results of t -test comparisons between independent means indicated that each of these three groups differed from one another. More external than the N1 group were both the ED sample, $t(294) = 4.65$, $p < .001$, and the JD group, $t(290) = 2.23$, $p < .05$. The ED group also scored in a more external direction than the JD group, $t(372) = 3.93$, $p < .01$.

Portions of the present article were conducted while the first author was affiliated with Virginia Commonwealth University.

Requests for reprints should be sent to Philip C. Kendall, Department of Psychology, Elliott Hall, 75 East River Road, University of Minnesota, Minneapolis, Minnesota 55455.

¹ Though the age-appropriate grade means reported by Nowicki and Strickland (1973) show a marked change from the fifth to sixth grade, the means of the present normal samples, also at these grade levels, were reasonably comparable.

Separate factor analyses resulted in eight factors for the N1 group (accounting for 67% of the total variance), five for the ED (59.2%), and six for the JD group (62.1%). The first factor emerging from the N1 group analysis contained four items that could appropriately be labeled *Generalized Expectancy*. A similar factor did not emerge from the ED or the JD data. Rather, the first ED factor was labeled *helplessness*, and the first JD factor was called *Superstition*. Representative of the other N1 factors were Intellectual Concern and Effort, and other ED factors were Persecution, Superstition, and Futility. The JD factors included Helplessness at Home, Helplessness with Friends, and Helplessness with Parents. Since the three analyses were rotated to the same varimax criterion, emergence of a general factor within the normal children's responses but not in the nonnormal groups should be attributable to differential characteristics in the subject groups.

A separate analysis of the amount of variability accounted for by each factor was conducted to compare the relative potency of factors in each group. In the N1 group, the factors did not account for different amounts of variance (largest $s = 1.66$). In contrast, the first factor to emerge in each of the nonnormal analyses (i.e., Helplessness from the ED data and Superstition from the JD data) accounted for a significantly greater amount of variance ($z = 2.16$, $p < .05$; $z = 2.02$, $p < .05$, respectively) than did the second or remaining factors.

Since whether a child is male or female in our culture is important regarding expectancies, a second sample of normal children (N2) that contained a large number of both males and females was obtained and analyzed for sex differences. A t test between independent means indicated that the females responded significantly more externally, $t(268) = 1.98$, $p < .05$, than males. In addition, both the entire N2 sample and the N2 females were more external than the N1 group, $t(376) = 2.87$, $p < .01$; $t(230) = 4.76$, $p < .01$, respectively, and the JD group, $t(454) = 2.00$, $p < .05$; $t(308) = 3.81$, $p < 0.1$, respectively, but not from the ED group (both $ts < 1$). The N2 males also were significantly more external than the N1 group, $t(250) = 3.12$, $p < .01$, and the JD group, $t(328) = 2.05$, $p < .05$, but, unlike the females, N2 males were significantly less external than the ED group, $t(332) = 1.71$, $p < .05$.

When the total N2 group responses were factor analyzed, the major factor—as in the initial N1 analysis—was appropriately labeled *Gen-*

eralized Expectancy. The remaining factors, however, consisted of only two items and could not be meaningfully labeled. The separate factor analyses for males and females resulted in seven and eight factors, respectively. For males, the major factor consisted of four items concerning Parental Fairness. For females, the major factor consisted of only two items (as did six of the eight factors) and was inconsistent regarding labeling. In regard to relative factor potency, the first male and female factors did not account for significantly different amounts of variance than the remaining factors.

Results of the initial group comparisons support the adjustment—locus of control hypothesis—that internals are better adjusted—since normals were significantly more internal than the two nonnormal groups. The N2 group, however, was significantly more external than the N1 group and not different from the ED group. Although N2 females were more external than the N2 males, one cannot explain the differences between the two normal groups on the basis of sex, since the percentage of females was similar in each group (N1 = 40%, N2 = 46%), and N2 males as a group were more external than the N1 group, composed of both males and females. Though sampling may account for the findings, the most parsimonious explanation may be that locus of control reflects relevant differences in children's life situations. That is, children's scores may indicate some effects of the situation on immediate responses to the scale (i.e., a state) as well as a stable disposition (i.e., a trait). To the extent that this were true or that other unknown factors were operating, one could anticipate that locus of control research with seemingly "normal" groups of children might yield contradictory findings.

In general, although the present results require replication, factor analyses indicated that locus of control in children is a multidimensional concept and that the patterning of factors differs among groups. One clear difference that emerged was in the *themes* that constituted the factors. For example, the main factor in both normal groups was a generalized expectancy theme, whereas the majority of the ED factor labels reflected feelings (e.g., Helplessness, Persecution, Futility), and the JD factors emphasized situations or environments (e.g., at Home, with Peers, with Parents).

Based on these findings, operation of the locus of control construct in different children's groups may be said to differ qualitatively. It seems pertinent then to question whether these qualita-

tive differences could affect quantitative comparisons. Or, stated differently, to what extent is one entitled to interpret scores on a particular inventory as reflecting the same construct for differing subject groups, especially when one is a nonnormal group?

Therapist and Group Contact as Variables in the Behavioral Treatment of Obesity

Kelly D. Brownell, Carol L. Heckerman, and Robert J. Westlake
Brown University/Butler Hospital

Obese females were randomly assigned to one of three experimental conditions: (a) a "standard" behavioral treatment (SBT) group emphasizing self-management techniques (Subjects attended group therapy meetings weekly for 10 weeks, then monthly for 6 months and were given a weight control manual.); (b) a group receiving the weight control manual via mail with little professional contact (MMC); and (c) a waiting list control condition. Results revealed a superiority of both treatment conditions over the control condition at posttreatment. SBT subjects did significantly better than MMC subjects at posttreatment but not at the 6-month follow-up. Weight loss for MMC subjects was minimal. The use of "do-it-yourself" treatment manuals is challenged.

The publication of do-it-yourself weight reduction books and manuals has proliferated in recent years. Unfortunately, the distribution of these materials has preceded experimental justification for their use.

Hagen (1974) found a bibliotherapy condition (manual via mail) to be as effective as a behavioral group therapy condition, both of which were superior to no treatment. However, a short follow-up and the use of a mildly obese population make the results difficult to interpret. Hanson, Borden, Hall, and Hall (1976) replicated Hagen's findings but found no treatment effects at a 1-year follow-up. The authors noted that only 4 of 38 subjects attained even 50% of their desired weight loss.

Fernan (Note 1) found that do-it-yourself dieters receiving little professional contact did not differ from subjects receiving no treatment. The present study was designed to remedy the problems with earlier investigations and to evaluate the effectiveness of self-administered diets.

Subjects were 29 females, at least 15 pounds (6.8 kg) or 15% overweight, who were randomly assigned to a standard behavioral treatment group (SBT), a group receiving a manual with minimal professional contact (MMC), or a no-treatment group. Subjects averaged 63.6% overweight, mean weight was 194.4 pounds (88.4 kg),

and average age was 48.7 years. In the SBT group subjects met weekly with a trained therapist for 10 weeks, then monthly for 6 months and were given the *Behavioral Weight Control Manual* (Brownell, Heckerman, & Westlake, Note 2). MMC subjects received the same manual and met six times to be weighed.

There were no pretreatment differences among groups for mean body weight or mean percentage overweight. At posttreatment, differences among groups were significant for change in body weight, $F(2, 25) = 10.36, p < .01$; change in percentage overweight, $F(2, 25) = 11.62, p < .01$; and the weight reduction quotient (pounds lost/pounds over $\times 100$), $F(2, 25) = 12.49, p < .01$. Newman-Keuls comparisons revealed that SBT and MMC subjects were superior to control subjects and that SBT subjects lost more weight than MMC subjects for all three measures of weight change ($p < .05$). At the 6-month follow-up, there were no differences between groups. Mean weight loss was 7.42 pounds (3.7 kg) for SBT subjects and 2.2 pounds (1.0 kg) for MMC subjects.

Both treatments were plagued by a lack of long-term effectiveness, and the weight losses could be considered only temporary. This was particularly true of the minimal contact group, which failed to produce even temporary weight loss. These results are consistent with previous findings that self-administered diets do not produce sustained weight loss.

The emotional hazards of unsuccessful dieting have been clearly documented (Stunkard & Rush,

Requests for reprints and for an extended version of this study should be sent to Kelly D. Brownell, who is now at the Department of Psychiatry, University of Pennsylvania, 205 Piersol Building, Philadelphia, Pennsylvania 19104.

1974), and there is preliminary evidence which suggests that periods of weight gain are characterized by substantial increases in blood pressure and serum lipid levels (Gordon & Kannel, 1973). It is possible that an ineffective diet is more dangerous than no diet.

In light of these potential hazards, and considering that the do-it-yourself dieter has little medical or psychological guidance, diets designed to be self-administered should be subject to controlled clinical investigation prior to distribution, and consumers should be educated as to the merits and drawbacks of specific programs.

COUNSELING IN COMMUNICATIVE DISORDERS edited by R. E. Harbauer, *Andrews Univ., Berrien Springs, Michigan*. (13 Contributors) This book comprehensively covers the psychological and emotional problems of persons with communicative disorders. Each chapter focuses on a particular communicative problem, giving a general overview of the disorder, counseling techniques and procedures, and suggestions for evaluation of effectiveness. Organic and functional disorders, the hearing impaired, financial aid, and other topics are explored. '78, 336 pp., 2 il., 1 table, \$16.50

ASSERTIVE TRAINING FOR WOMEN (2nd Ptg.) by Susan M. Osborn, *Bellevue Community College, Bellevue, Washington*, and Gloria G. Harris, *Univ. of Washington, Seattle*. The authors review ways in which women are socialized to be submissive and dependent and they evaluate the usefulness of traditional and alternative psychotherapeutic approaches. Specific areas of application explored include improvement of social interactions, enhancement of sexual functioning, entrance and advancement in the job market, and relief of emotional depression. '78, 216 pp., 12 il., 7 tables, cloth-\$10.50, paper-\$7.95

THE CLINICAL APPLICATION OF PROJECTIVE DRAWINGS (5th Ptg.) edited by Emanuel F. Hammer, *New York Univ., New York City*. (14 Contributors) This book provides a grounding in the fundamentals of the subject and goes on to consider differential diagnosis, psychodynamics, conflict and defense, psychological resources as treatment potentials, and projective drawing usage in therapy. '78, 688 pp., 360 il., \$21.75

PUPIL PERSONNEL STRATEGIES AND SYSTEMS by Robert W. Ferris, *Cherry Hill Public Schools, Cherry Hill, New Jersey*. This comprehensive text bridges the gap between the theoretical and the practical in the pupil personnel field. Chapters are included on management models, administrative systems, group counseling, career development, use of computers, and assessment and evaluation. Psychologists, counselors, administrators, social workers, learning specialists, and related professionals will all benefit from the depth and clarity of this thorough examination of pupil personnel strategies and systems. '75, 264 pp., 22 il., 5 tables, \$14.95

STRATEGIES FOR HELPING STUDENTS by Calvin D. Catterall, *Staff Development Consultants, Columbus, Ohio*, and George M. Gazda, *Univ. of Georgia, Athens*. All available strategies for helping students are presented. They are grouped into four areas of concentration: strategies for developing academic/intellectual skills, corrective/remedial interventions, strategies for developing humanistic/life skills, and corrective/therapeutic interventions. The final chapter explains the process of selecting the strategy most likely to succeed with a specific need. '78, 416 pp., 5 il., 38 tables, \$18.75

PERSONALITY PROJECTION IN THE DRAWING OF THE HUMAN FIGURE: A Method of Personality Investigation (10th Ptg.) by Karen Machover, *Dept. of Hospitals, New York City*. This original technique for human figure drawing analysis combines the psychology of expressive movement with a fresh approach to functional and symbolic significance. Illustrative case studies demonstrate the manner of integrating the data to form a coherent picture of the personality. '78, 192 pp. (5 1/2 x 8 1/2), 18 il., \$8.50

THE PSYCHOLOGICAL REHABILITATION OF THE AMPUTEE by Lawrence W. Friedmann, *Nassau County Medical Center, East Meadow, New York*. This text begins with an historical and cultural analysis of amputation and its effects on the individual. Other chapters focus on patient reactions, prostheses, social aspects, the phantom limb phenomenon, the limb-deficient child, and the occurrence and treatment of phantom pain. Analyses of psychological responses to amputation are presented in this book with unprecedented depth and insight. '78, 176 pp., 13 il., \$13.50

DIAGNOSIS AND REHABILITATION IN CLINICAL NEUROPSYCHOLOGY by Charles J. Golden, *The Univ. of South Dakota, Vermillion*. This book offers a unique integration of the theoretical basis, experimental research, and clinical and diagnostic procedures of the emerging field of clinical neuropsychology. The main portion of the text is concerned with clinical test procedures and with ways in which psychological testing can be used to identify a brain disorder, localize the area of a lesion, and determine underlying causes. Evaluation of Psychological Service Delivery Programs

Special Issue of Professional Psychology

Evaluation of Psychological Service Delivery Programs is the title of a special November, 1977 issue of Professional Psychology. Editor Allan Barclay and guest Co-editors Bob and Evelyn Perloff have assembled a distinguished collection of articles that brings readers up to date on the evaluation of psychological services. The issue addresses the need to justify the effectiveness of service delivery programs not only in terms of cost but more importantly in terms of human benefits.

Sample Topics and Contributors

A sample of the topics and contributors appearing in this issue includes: Theodore Blau on quality of life; Nicholas Cummings on psychotherapy; Howard Blane on alcoholism; S. B. Sells and associates on drug abuse, and NIMH's Bertram Brown, Benjamin Liptzin and James Stockdill on the federal view of mental health program evaluation.

Chicago Conference on the Psychology of the Self

October 13, 14, & 15
1978
Ritz-Carlton Hotel
Chicago

A recent scientific event in the fields of psychology and psychiatry has been the emergence of the Psychoanalytic Psychology of the Self. In order to acknowledge and appraise the significance in psychoanalysis of this new development, a conference will bring together a group of mental health professionals from the United States and Europe. The conference will examine self psychology, identify its current problem areas, and outline plans for further development and applications. The conference program consists of six symposia with discussants and related workshops, dealing with the following topics:

- ☆ Self Psychology and the Concept of Health
- ☆ Does the Psychology of the Self Narrow the Gap Between Psychoanalysis and the Other Sciences of Man?
- ☆ Self Psychology and the Concept of Psychopathology: A Case Presentation
- ☆ Psychoanalytic Developmental Psychology: An Integration of Theories
- ☆ Psychoanalysis of the Self and Psychotherapy
- ☆ Concluding Remarks and Future Directions

The Conference Planning Board is composed of members of the Institute for Psychosomatic and Psychiatric Research and Training of Michael Reese Hospital and Medical Center, and the Institute for Psychoanalysis in Chicago. Please note that attendance will be by advance registration only, and that registration will be limited.

For registration information, write:

ANNOUNCING A BREAKTHROUGH IN THE MEDITATIVE-RELAXATION FIELD...

*CSM Instructor's Kit: Created and narrated by Patricia Carrington, Ph.D., Dept. of Psychology, Princeton University (the technique described in her book **FREEDOM IN MEDITATION**)*

***CONTENTS:** 3 Meditation training tapes; 3 clinical lectures; 82 page semi-programmed-instruction text; instructor's manual.*

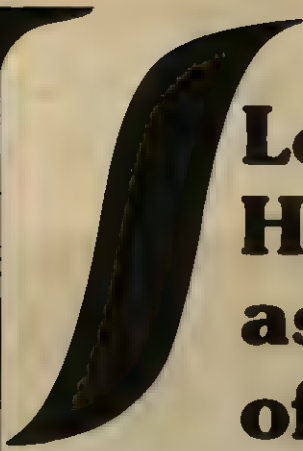

A fully automated, self-regulating course covering all elements involved in Clinically Standardized Meditation (CSM), motivational tapes, exercises, reinforcement aids and supervisors' guidance.

"Superbly done. . . highly effective. . . will be a major tool for clinicians and researchers."

Arnold A. Lazarus, Ph.D.

Learned Helplessness as a Model of Depression

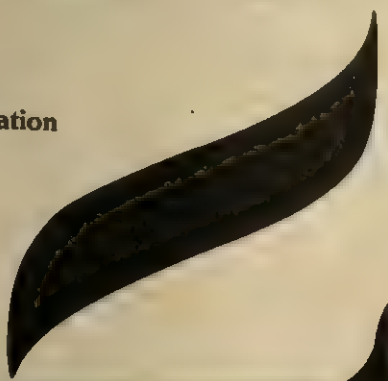

**Special issue of the
Journal of Abnormal Psychology,
February 1978.**

The issue serves as a forum to investigate the validity and adequacy of the learned helplessness model of depression in humans and includes both critical and supportive theoretical and empirical articles with comments.

L. Rowell Huesmann is guest editor. Richard A. Depue, Martin E. P. Seligman, Charles G. Costello, Robert C. Smolen, and Alexander M. Buchwald are among the contributors.

Copies of the special issue are available at \$6 each, prepaid. Discounts on bulk orders are also available. To order single copies or for more information on bulk orders write:

American Psychological Association
1200 17th Street, N.W.
Washington, D.C. 20036**

For the First Time...

an easy reading, practical, step by step guide to

A must for

- Full and part-time private practitioners.
- Those who have ever even considered entering private practice.

"Reduces the chance of failure or disappointment."

An entertaining, well organized book complete with worksheets, plans, and practice approaches to the everyday "nuts and bolts" business aspects of private practice.

MARK H. LEWIN, an ABPP Diplomate, distinguished author and editor, and founder of a thriving independent psychological service center, gives step-by-step procedures for:

- Assessing your readiness for private practice
- Preplanning the practice
- Setting up the office
- Developing new referrals
- Managing your time
- Effective use of lawyers and accountants
- Evaluating the practice as it develops
- Budgeting, fee setting, controlling costs and tax expenses

PSYCHOLOGICAL TEST SPECIALISTS

Exclusive publishers and distributors of selected psychological tests

Quick Test (QT)

A very quick and satisfactorily reliable screening test of intellectual ability (8 to 12 minutes total time in all three forms). Words are defined non-verbally by choice among drawings. Suitable for any person (no matter how physically disabled) who can signal a yes-no response in any way. Covers intelligence levels from two years to superior adult. Excellent for building rapport, and for quick testing before and after any procedure. \$16.00 for set of materials

Memory-For-Designs Test (MFD)

Simple drawing test of perceptual-motor coordination, serving as extremely sensitive detector of brain injury of many types. \$17.00 for set of materials

Group Personality Projective Test (GPPT)

Multiple-choice questions about ambiguous stick-figures make possible rapid and effective measurement of significant, factor-analytically isolated aspects of personality. \$27.00 for set of materials

Id-Ego-Superego Test (IES)

Subtests give independent estimates of personality components from a modified psychoanalytic point of view. \$43.50 for set of materials

Kahn Test of Symbol Arrangement (KTSA)

Uses symbolic plastic objects which are arranged and sorted; validly discriminates among normals, neurotics, brain-injured, and psychotics, and indicates accompanying personality dynamics. \$50.00 for set of materials

Full-Range Picture Vocabulary Test (FRPV)

Brief test of intelligence in two forms using the same 16 plates. Words are defined by choosing pictures. Valuable for intelligence screening, and with the physically handicapped. \$15.00 for set of materials

Proverbs Test (PT)

Group and individual forms determine similarity of thought processes to those of various normal and clinical groups. Highly sensitive indicator of psychotic processes. \$13.00 for kit

Vocational Apperception Test: Advanced Form (VAT:ADV)

Separate series of plates showing male and female college-rated occupational activities, accompanied by explanation of use and interpretation as a projective test. \$14.50 for set of materials

Famous Sayings (FS)

Agreement with proverbs, aphorisms, and folk sayings is analyzed to determine personality structure. Particularly useful in personnel selection. \$13.00 for kit

It Scale For Children (ITSC)

An experimental picture scale for measuring sex role preference in children. \$30.00 for set of materials

Kahn Intelligence Tests: (KIT:EXP)

Relatively culture-free intelligence tests requiring no reading or writing. Supplementary scales for assessment of intelligence of the blind, ability in concept formation, recall, and motor coordination. One scale can be administered by sign language. \$52.00 for set of materials

PSYCHOLOGY

AMERICAN PSYCHOLOGICAL ASSOCIATION
ISSN 0022-006X

INSTRUCTIONS TO AUTHORS

Style of manuscripts. Manuscripts must be prepared in the style described in the *Publication Manual of the American Psychological Association* (2nd ed.). Instruction on tables, figures, references, metrics, and typing (all copy must be double-spaced) appear in the Manual. Authors should submit manuscripts in triplicate and should keep a copy to guard against loss.

Abstracts. Manuscripts of regular articles must be accompanied by an abstract of 100-175 words. Manuscripts of brief reports must be accompanied by an abstract of 75-100 words. All abstracts must be typed on a separate sheet of paper.

Brief Reports. The *Journal of Consulting and Clinical Psychology* will accept Brief Reports of search studies in clinical psychology. The procedure is intended to permit the publication of soundly designed studies of specialized interest or limited importance which cannot now be accepted as regular articles because of lack of space. Several pages in each issue will be devoted to Brief Reports, published in the order of their receipt without respect to the dates of receipt of the regular articles. Most Brief Reports appear in the first or second issue to go to press following their final acceptance.

An author who wishes to submit a Brief Report:

1. Sends the Brief Report, limited to two printed pages and prepared according to the specifications given below.

2. Agrees not to submit the full report to another journal of general circulation.

Specifications. The Brief Report should give a clear, condensed summary of the procedure of the study and as full an account of the results as space permits.

To ensure that a brief report does not exceed two printed pages, follow these instructions for typing: (a) Set typewriter to a 48-space line. (b) Type text. (c) Count all lines except abstracts, title, and by-line, including acknowledgments. If you have exceeded 185 lines, shorten the material. (d) If your brief report barely exceeds 75 lines (one printed page), try to edit to 75 lines exactly. Reports slightly exceeding one page will be edited for length in order to use space economically.

In Brief Reports, headings, tables, and references are avoided or, if essential, must be counted in the 75 lines. This journal no longer requires an extended report, but, if one is available, each Brief Report must be accompanied by the following footnote:

Requests for reprints and for an extended report of this study should be sent to John Doe (give the author's full name and address).

The footnote should be typed on a separate sheet and *not* counted in the 75-line quota.

Garfield Appointed Editor, 1979-1984

The Publications and Communications Board of the American Psychological Association announces the appointment of Sol L. Garfield as Editor of the *Journal of Consulting and Clinical Psychology* for the years 1979-1984. As of January 1, 1978, manuscripts should be directed to the Editor-elect:

Sol L. Garfield
Department of Psychology
Washington University
St. Louis, Missouri 63130

Preface

Four of every five manuscripts submitted to this journal in recent years have been rejected. Although rejection can occur for many reasons, most of the unsuccessful manuscripts were returned because of serious methodological weakness in the research. Many of these errors of method were fundamental and glaring. Indeed, it is not possible to complete an editorial term without inferring reluctantly that current doctoral training in research, as reflected by recent submissions to this journal, is deficient to the point of being disastrous.

This unfortunate inference has led to this special issue, which is intended to be a resource for behavioral scientists working on problems of clinical psychology. Each contribution that follows describes and discusses the major methodological aspects of a particular topic area such as smoking or addiction. The topic areas have been selected because of the frequency with which they have stimulated contemporary research investigation.

Readers may note that at some points contributors have raised issues that may appear elementary. This has been done not out of an insensitivity to the level of sophistication of the journal's readers, but because our experience reviewing manuscripts has made it clear that many investigators are misinformed on some basic matters.

It is the hope of the Editor and contributors alike that this issue of the journal will be of some lasting value to those who engage in the difficult and demanding task of clinical research.

Research Problems in Clinical Diagnosis

Sol L. Garfield

Washington University in St. Louis

This article discusses some of the problems and deficiencies apparent in past research on clinical diagnosis. Among the important issues discussed are those pertaining to sampling problems with regard to the clinical subjects studied, adequacy of control groups, base rates, clinical versus statistical significance, lack of cross-validation, and problems due to reliance on inadequate schemes of classification. Some cautions and suggestions in terms of future research are also discussed.

Although interest among clinical psychologists in clinical diagnosis and related activities has appeared to diminish relatively in recent years, interest in diagnostic problems remains, and a number of studies on such problems are conducted yearly. Although over the years we have had an opportunity to become better acquainted with methodological problems concerning research in this area, it would appear as if rather limited advantage has been taken of this opportunity. I will discuss a number of methodological inadequacies that I have encountered in reviewing manuscripts for this and other journals, as well as in the published literature.

The term *clinical diagnosis* does not appear to have a precise meaning, and consequently, this should be acknowledged at the outset. Although in the past, this designation frequently has referred to psychiatric diagnosis, or a nosological label taken from the *Diagnostic and Statistical Manual* prepared by the American Psychiatric Association (1968), such a delimitation has not been exclusive. Many psychologists have not limited themselves in this manner, preferring to use other schemes, formal or informal. Some have preferred the term *assessment* to that of *diagnosis*. Others have preferred to rely on personality descriptions and on the inferred psychodynamics of the individuals appraised.

I will not debate the issue here of what clinical diagnosis really is, but I will include in my discussion references to research that involves the clinical assessment, diagnosis, comparison, or categorization of individuals being appraised or studied for clinical purposes. The presentation is organized around several topics that have appeared to be of particular concern.

Sampling Problems

One of the most frequent and serious problems encountered in diagnostic research pertains to the sample of subjects or patients used in particular investigations. This actually is a broad categorization for a variety of problems. One critical issue pertains to how far one can generalize from the findings obtained with a certain sample of subjects purported to represent a given type of disorder or diagnosis. Ostensibly, at least, findings secured from a particular sample representative of a given category of disorder presumably have relevance for other comparable samples. The question then is, how does one define both the sample studied and the other samples or populations to which the results are supposedly applicable?

Unfortunately, there are no true standard reference measures that can be used to define a particular clinical group of subjects, and the diagnostic terms used leave much to be desired. Consequently, it is exceedingly important that the sample be selected with great care and that as much useful descrip-

Requests for reprints should be sent to Sol L. Garfield, Department of Psychology, Washington University, St. Louis, Missouri 63130.

tive information as possible be provided concerning the sample. Many manuscripts, as well as a significant number of published articles, fail to provide even such basic data as the sexual composition of the sample, let alone other attributes of importance. Such aspects as age, length of hospitalization, frequency of hospitalization, marital status, work history, previous treatments, family resources, education, intelligence, type of ward the patient is on, whether he or she is receiving medication, the type of medication, and the like, are all potentially important variables that may influence test performance, treatment outcome, and similar variables. It should be apparent that significant variation on some or many of these variables between studies limits the reliability of the results secured and the drawing of conclusions that may have broad applicability.

The problems referred to above are particularly visible when samples of modest size are drawn from institutional settings that vary widely on a number of dimensions. Patients in university or private hospitals generally are quite different from those in state or Veterans Administration psychiatric hospitals, and generalizations from one setting do not fit the other settings, even though the patients may all carry a diagnosis of schizophrenia. For example, in a previous study of prognostic scales used in research on schizophrenic patients, we were unable to secure an adequate number of "reactive" or good-prognosis patients in the state hospital where we were conducting our study and had to secure patients from a city hospital, which had fewer chronic patients (Garfield & Sundland, 1966).

Although sample size is also of some importance, since small scale studies are more prone to produce findings limited in reliability, size alone is not sufficient. The selection of subjects and sample specifications is clearly of prime importance. If one is studying or comparing selected types of disordered behavior, the criteria used in selecting subjects should be explicit and the procedures used should be ones for which the reliability and validity are known or available, and meet commonly accepted standards. Particularly when studies are conducted on groups based on psychiatric diagnosis, it is essential that

how the diagnoses were derived be clearly described and that other supporting selection criteria be used. Diagnoses based on old records and provided by different psychiatrists are usually not sound or reliable bases for subject selection.

A related problem concerns the matter of randomization of subject selection. Were the subjects selected at random from a previously selected pool of available subjects or were they selected because they were not on drugs, were in a special ward, were considered co-operative, or in some other manner were really not "typical subjects"? Such selectivity can obviously bias the results obtained and can limit their generalizability.

Selection of subjects on the basis of a single scale may also not be adequate, particularly if the subjects are considered to represent a particular diagnostic group. For example, not all subjects who score 70 or higher on a scale of the Minnesota Multiphasic Personality Inventory (MMPI) resemble groups diagnosed on other criteria as schizophrenic, depressed, and so on. College students who secure such scores may or may not be clinically depressed, psychotic, and so forth, and comparisons with actual clinical populations may therefore not be warranted.

It would seem clearly desirable to use more than one procedure or method to establish the diagnosis of the subjects to be used in any research study in which the diagnosis is considered to be a significant variable. Psychiatric or clinical diagnosis should be supplemented by other criteria such as scores on appropriate tests or standardized rating scales. In the case of depression, for example, scores on the MMPI, the Hamilton Rating Scale (Hamilton, 1960), and the Beck Depression Inventory (Beck, 1972) could be used in addition to clinical diagnoses. Furthermore, clinical diagnoses, preferably, should be based on diagnoses secured from two or more clinicians with a reasonably high indication of reliability between them. If such procedures are followed, there is greater assurance of the reliability of diagnosis as well as several external or operational reference points in defining the samples used. To be sure, extra effort may be required to carry out such procedures, and, to a certain extent,

such procedures might reduce the size of potential samples and raise new issues of selectivity and limited generalizability. However, the samples would be more clearly defined, and the dangers of relying exclusively on somewhat haphazard means of classification would be lessened. In the long run, at least one would hope, the conflicting results obtained with the use of diffuse, unclear, and unreliable diagnostic categorization might diminish.

Another issue that is sometimes apparent concerns the selectivity of a patient sample in order to match it with a control group. If, for example, the control group has an average IQ of 98, an average educational attainment of 10th grade, or is composed primarily of ward attendants, a subject sample selected to match it on one or more of these variables may be a highly selected and unrepresentative sample of the patient group that these people are supposed to represent. They are not typical patients of a particular diagnostic group, and broad generalizations to other more randomly selected groups are not justified. For example, in one study of mine of patients diagnosed as schizophrenic, very different patterns of performance on the Wechsler-Bellevue Scale were secured for patients differing in education and IQ (Garfield, 1949). Furthermore, comparisons of samples of schizophrenic patients studied in different investigations, which differed noticeably in terms of mean IQ, also revealed significant differences on test patterns among these samples. In other words, there were as many significant differences between the various samples of schizophrenic patients as there were between a given sample and a normal group of control subjects. A recent study of brain-damaged adults also revealed significant differences due to education on a battery of tests (Finlayson, Johnson, & Reitan, 1977).

The relative influence of social class variables on samples of subjects is another matter that needs to be carefully appraised in each study. As Meehl (1971) has pointed out, the tendency among social scientists to view correlations uncorrected for social class as automatically spurious is unjustified, unless a clear case can be demonstrated that a causal relationship exists between social class and the

correlated variables in the specific instance. In some cases, this may be so, but in others, the so-called nuisance variable may be of little importance. If there is doubt, the investigator can provide both corrected and uncorrected correlations as one means of attempting to evaluate the possible importance of social class variables. (See Meehl's, 1971, article for a more extended treatment of this issue.)

The selection and specification of subjects used in research on clinical diagnosis is thus a matter of primary importance, and would-be investigators should give careful attention to the issues discussed in the preceding paragraphs. In the final analysis, the results can be no better than the type and representativeness of the subjects used.

Some of the problems pertaining to how clinical diagnoses are secured will also be mentioned briefly here, although they could be accorded a separate section. Most clinical psychologists are quite aware of the problem of diagnostic reliability, and this issue need not be reviewed in any depth here (Garfield, 1974). However, because of its relevance to much research on clinical diagnosis, some reference to this matter is pertinent here.

In an earlier section of this article, some mention was made of the importance of fully describing the sample studied and how it was selected. One aspect of sample description concerns the matter of diagnosis. How were the patients diagnosed, by whom, and when? These are all pertinent questions that influence sample specification and, ultimately, the results secured and the conclusions drawn. If the diagnosis is made by one clinician, how representative are his or her diagnoses? In one study comparing three psychiatrists working in the same hospital with comparable groups of patients, it was found that one of the psychiatrists classified two thirds of his patients as schizophrenic, whereas the other two psychiatrists classified 22% and 29% of their patients as schizophrenics (Pasamanick, Dinitz, & Lefton, 1959). Thus, some attention has to be paid to the reliability of diagnosis and comparability of diagnoses among different studies.

Diagnoses made at the time of intake or admission to the hospital may also differ from

those made at a later time when more opportunity for observation and study is available. Similarly, diagnoses reached at a formal staff conference or with the help of teaching consultants may be different from those made by a single clinician. Diagnoses based on psychological tests may also be different from those based on other data sources. However, little or no information on such relevant matters is provided in a large number of studies. The usual statement is something like this: "Sixty-four patients diagnosed as schizophrenic were selected for study." This certainly does not provide adequate information about how the diagnoses were made or by whom they were made. Consequently, specification of how diagnoses were reached is of some importance in estimating the confidence one can place in the diagnoses secured and also in evaluating the comparability of research studies. Since the behavior of patients also changes over time, there is also a question about the suitability of diagnoses that were reached some time prior to the current investigation. There are, thus, a number of apparently minor but nevertheless important considerations that pertain to the matter of diagnosis.

Proper Control Groups

Another problem frequently encountered in research reports concerned with clinical diagnosis pertains to the appropriateness of the control groups used. Although we are relatively more sophisticated about such matters now than we were in the past, problems of appropriate controls are still evident. Obviously, a group of patients that has been hospitalized for some time should not usually be compared with a group of apparently normal college students, but comparisons approaching this type have been made.

This problem is of special significance when the focus of a particular investigation is on clinical diagnosis or on the specification of patterns of performance of a specific category of patients or subjects. If the results of the study are to have any clinical significance in the practical sense, then the experimental group must be compared to other clinical groups with which they would normally be

compared in the actual clinical situation. Comparisons of test performance or other measures of a sample of patients diagnosed as schizophrenic should be made with other clinical groups normally seen in that clinical situation and in approximately the usual proportions. In a clinical or hospital setting in which a clinical diagnosis or evaluation is sought, the problem is rarely one of comparing the given patient to a normal population. Rather, the issue is one of differential diagnosis and appraisal. Is there any suggestion of psychotic disturbance or of possible brain damage? How serious is the thought disturbance or depression manifested by the patient? In trying to reach answers to such questions, the clinical psychologist is considering patterns of various types of psychopathology and is not comparing the patient's performance primarily to the performance of normally adjusted individuals. Thus, in studying a diagnostic pattern for possible utility in clinical diagnosis, the investigator should compare the results of the particular clinical group of interest with those of other diagnostic groups that are usually encountered in practice and from whom the aforementioned group is to be compared or differentiated. For purposes of clinical diagnosis, it would seem efficacious to have a control group made up of the proper mix of the other diagnostic groups that are normally encountered in the particular setting or of several groups representing the types of disorders that are most frequently confused with the group under study.

Similar to the issue mentioned earlier with regard to the selection of the sample of subjects for investigation, the investigator should provide adequate information on all groups of subjects, such as how they were selected and from which subpopulation they were drawn. For example, if a control group of 30 patients was selected for purposes of comparison with the group under study, why and how were these subjects selected and from what number of comparable subjects were they drawn? If they were the only ones who had certain data or test scores available, what were the reasons for this particular state of affairs? How selective is the group, and how representative are they of supposedly similar subjects? Selective bias may greatly impair

the kinds of conclusions that may be drawn and the extent to which generalization to other samples and populations is possible.

It should be reasonably obvious also that whatever control group or groups are used should be comparable on the variables of importance for a particular investigation. When cognitive tests are used, the groups should show some comparability in terms of level of ability, education, and age, since these may all affect performance. However, if one's particular focus is the diagnosis of mental retardation, such comparability may not be necessary or meaningful. Length of institutionalization, drugs, type of ward, degree of cooperation, and other such attributes may also be variables of importance.

In essence, therefore, considerable attention should be given to the selection of adequate and appropriate control groups in research on clinical diagnosis. Although this seems particularly relevant to matters of differential diagnosis and related problems, the issue of appropriate control groups also applies to more experimental or theoretical studies of psychopathology—at least as far as I am concerned. Numerous studies of various psychological functions in schizophrenic subjects have compared the latter mainly with normal controls. Although this may have some value at a certain stage of investigation, it is ultimately of limited value if one is interested in demonstrating particular patterns of response or thought in a given clinical disorder. What the investigator is actually trying to discover or demonstrate are response patterns that characterize a pathological group. Whether these patterns are distinctive of the particular type of pathology in question can only be demonstrated if the performance of the pathological group is compared with other pathological groups of comparable severity. In this particular instance, other psychotic groups would appear to be the most adequate control groups.

Clinical Versus Statistical Significance

Surprisingly, a number of basic statistical and clinical considerations appear to get slight consideration from would-be authors and investigators. Those that have been noted with some frequency will be discussed.

In at least a noticeable number of manuscripts, significant correlations or differences at the .05 level of significance are reported, with little attention paid to the number of significance tests performed. Although it should be apparent that the interpretation of the significant findings secured is directly related to the number of statistical tests performed, this stricture is not always observed. If 35 comparisons or correlations are performed and 2 are found to be at the magic .05 level of significance, it seems clear that these results are so close to a chance occurrence that little should be made of them. However, some investigators generally play down this aspect of their results and emphasize their potential significance. In a similar fashion, post hoc analyses are sometimes treated as if explicit hypotheses were being tested. Obviously, different considerations enter into such analyses than when a specific hypothesis, stated in advance of the investigation, is being tested. Although these matters are considered to be rather basic ones in instruction on experimental design and statistical analysis, somehow the lessons on these topics are either not learned well or are quickly forgotten.¹ When investigators emphasize significant findings that they have not predicted in advance but that are noted after the investigation has been completed, they are essentially capitalizing on chance occurrences. For the results to be taken seriously, they should be replicated on a new sample of subjects.

A related issue concerns the practical or clinical significance of findings that are clearly significant statistically at the .05 or even at the .001 level of significance. It would appear from numerous reports of all kinds of studies that researchers have been led to worship at the shrine of statistical significance. Perhaps this is a result of the emphasis placed on securing "positive" results and the dread of not being able to reject the null hypothesis, particularly with reference to doctoral dissertations. Happy is the person who secures "positive results" at the .05 level

¹ These matters along with some procedures for estimating the probability of securing spurious findings are discussed by Hays (1963, pp. 488-489).

of significance, regardless of whether the results are of some potential practical or social value. Of all the limitations that I have encountered in reviewing manuscripts for several journals over a period of years, the emphasis on statistical significance and the disregard of practical psychological significance is probably the most frequently encountered.

There are several aspects of this problem that should be emphasized here even though most of them may be considered to be obvious or elementary. The fact that they occur with some frequency makes such an emphasis permissible and warranted.

Clearly, a researcher must examine his or her data to see if the results obtained are due to chance. A statistical test of the differences secured between clinical groups or of correlations obtained on certain measures and designated criteria for a specific diagnostic category or categories is a necessary procedure to estimate the influence of chance on the results secured. No criticism of this procedure is implied here. However, one should recognize that this represents only one of the necessary procedures for appraising the results. Such a statistical test informs us of the probability that our results may be explained by chance occurrences. If our results are significant at .05 level of significance, our usual interpretation should be that there are only 5 chances in 100 that the obtained results may be attributed to chance. The findings, of course, could be due to chance, but the odds would appear to be against it. However, all one can reasonably conclude is that the findings do not appear to be due to chance and that if the study were repeated, we might expect the findings to be comparable to those obtained initially. Whether the results obtained have any clinical usefulness cannot be determined by the statistical tests alone. Other appraisals must be made for this purpose.

Before going on to discuss the matter of the clinical significance of research data, it is worth reiterating some other elementary considerations pertaining to statistical manipulations and their meaning. Statistical tests tend to be very much influenced by the size of the samples used and by their variability. Obviously, large samples generally would be less influenced by selective and chance vari-

ables than would very small samples, and, thus, findings that are small in actual magnitude may be statistically significant in the former instance, whereas they would fail to attain significance with smaller samples. For example, with samples of about 30 subjects, correlations have to be in the neighborhood of .35 or so in order to reach significance. In contrast to this, with a sample of several hundred subjects, a much lower correlation, in the neighborhood of .10, may be statistically significant, although the amount of predicted variance in the scores is of no practical significance. Thus, besides the level of significance, we must also consider the size of the sample and the actual amount of variance accounted for by the correlation coefficient if we are to interpret the findings in terms of their broader significance or utility. Moderately high correlations that are not statistically significant would appear to be of little value, and highly reliable but low correlations would also appear to be of rather limited value. In a similar fashion, low variability within groups of subjects generally increases the probability of securing statistically significant results, and although small standard deviations offer the possibility of useful discrimination between different clinical groups, the actual utility of the measures or comparisons used requires further analysis of the actual data secured.

Even though there are occasional discussions of the difference between clinical and statistical significance in the published literature (Lick, 1973), the importance of this topic either does not get enough attention during the graduate training of future clinical researchers or the occasional references to it have a relatively weak impact on those to whom it is directed. Many investigators appear content to rest on their statistical laurels and not to worry overly about the actual practical value of their results.

Clearly, as indicated earlier, an investigation can be conducted to test a theoretical proposition or hypothesis when practical considerations are not of primary importance. However, if the investigator in his or her discussion of the results obtained implies some potential clinical significance for the data, then he or she should provide some additional

support for the inferences that go beyond the fact that statistically significant results were obtained. The kind of analyses that should be done will be described briefly in the next few paragraphs.

There are several aspects of the research data that should be examined in terms of their potential clinical significance. For example, regardless of the mathematical procedures used to test hypotheses within a statistical model, it is also important to know how much of the variance is accounted for in terms of the particular variables studied. For practical purposes, as well as theoretical ones, this is a very important consideration, but it is very frequently omitted in the discussion of results. In the case of correlational data, it is relatively simple to square the coefficient of correlation and secure an estimate of the amount of variance accounted for by the particular set of correlates. With other methods of analysis, the implications may not be as readily apparent, but it is equally important that an estimate of the variance accounted for by the experimental manipulation be provided.

The importance of such analyses can be illustrated from some recently published reports, as well as from reviews of other unpublished material. Particularly when large samples are used, the author should feel obligated to stress the implications of his/her findings in terms of the variance accounted for by the variables under study. For example, in the published report of the current activities and preferences of a sample of 855 clinical psychologists (Garfield & Kurtz, 1976), numerous findings at the .01 level of significance or better were secured. Some may have been the result of the numerous comparisons made, but the sample size appeared to be of some consequence in this regard. Correlations of .10 that were highly significant statistically were consequently considered to be of little practical importance, since they accounted for only 1% of the variance. In another published study of over 1,000 clients in a number of community mental health centers, several correlations of around .10 were reported as highly significant, even though they were obviously of little significance clinically or socially (Sue, McKinney, & Allen, 1976). For example, the correlation

between diagnosis and premature termination was .10, and this was significant at the .001 level of confidence. However, by itself, such a significant finding accounts for a negligible amount of the variance.

In another study, a mean difference of 4 on one subtest of the Wechsler Adult Intelligence Scale (WAIS) was obtained between two different administrations of the test to a sample of schizophrenic patients. This difference was reported as being significant at the .05 level of confidence, and the author went on to offer some detailed conclusions pertaining to this "significant" finding. Results of such magnitude, however, would not appear to be of much practical value.

Apart from going beyond the obtained levels of statistical significance to report the amount of variance accounted for by the variables studied, other analyses may be required if the data are presumed to have some value for clinical diagnosis. The means and standard deviations for the clinical samples studied should be reported, and the extent of overlap of the distributions should also be clearly stated. Of value also for clinical diagnosis are the number of subjects who would be correctly diagnosed or classified by the diagnostic procedures evaluated and those who would be misclassified—that is, data on false positives and false negatives. These are certainly important data for any purportedly effective diagnostic procedures, but they are not always secured or provided in reports of research in this area. It should be apparent that a particular diagnostic technique may differentiate two or more clinical groups at the .05 level of significance but yet produce so many false positives or negatives that it has very limited clinical utility. It would appear incumbent on investigators to analyze their data in terms of such considerations and to present their analyses in a clear fashion.

Base Rates

Another problem in some types of research on clinical diagnosis pertains to the old issue of base rates. Even though this important matter was raised some years ago and is not an unfamiliar topic in either the areas of diagnostic assessment or psychotherapy (Gathercole, 1968; Meehl & Rosen, 1955),

at least a certain number of studies appear to disregard it even when it is clearly relevant. Consequently, although the matter of base rates is not a new issue nor even a complex one, I will devote some space to it and provide a few examples of what is involved.

I can start this brief discussion by referring to an earlier experience of my own. Working as a clinical psychologist in a Veterans Administration hospital 30 years ago, I collected some Rorschach test data on a moderate sample of patients who had been diagnosed as schizophrenic by the clinical staff. I compared my diagnostic impressions based on the test data with the clinical diagnoses on these patients and, among other things, noted that my diagnoses agreed with the staff diagnoses in about 67% of the cases. I prepared a paper on this study and submitted it to the branch chief psychologist, who at that time was David Shakow. He returned it to me with his comments. Among the suggestions he made was that I secure the base rates for diagnoses of schizophrenia in my hospital. I was rather reluctant to comply with his suggestion but did a quick survey of admissions for a limited time and discovered that the number of cases diagnosed as schizophrenic was just about 67%. In other words, my diagnostic work did not exceed the base rate for diagnoses of schizophrenia, and diagnosing every admitted patient as a schizophrenic would have been as accurate as diagnoses derived from my Rorschach examinations.

The matter of base rates, thus, is of some consequence, and it is certainly a factor that must be appraised in evaluating certain kinds of research on clinical diagnosis. Apart from the fact that diagnostic procedures to be effective must clearly exceed the base rates for a particular disorder, attention to such matters along with attention to false positives and negatives indicates the potential difficulties in using diagnostic procedures for disorders in which the incidence is very low, as is the case for suicide. In the latter instance, a diagnostic or predictive measure must be extremely effective in discriminating the specific type of cases being evaluated if they are to be clinically useful.

Thus, for specific kinds of problems per-

taining to differential diagnosis or prediction, it appears essential for the researcher to provide data on the base rates for the disorders of interest and to clearly show the advantages as well as the disadvantages for the procedures being evaluated. Listing the percentage of correct hits or diagnoses obtained by a particular diagnostic technique is not sufficient. Along with other criteria, attention must be paid to the matter of base rates.

Inadequate Data Presentation

The present designation includes a variety of frequently small but, nevertheless, important oversights that are apparent in at least some manuscripts. Among these are such matters as not providing basic information on the measures or scales used, necessary information on important variables, how diagnoses were secured, how the subjects were selected, and similar aspects. The examples to be discussed will not be exhaustive but rather will illustrate the kinds of problems encountered when such information is not included in the report.

In the current era in which a large number of patients, both inpatients and outpatients, are receiving medication of various kinds, it is extremely important that this information be provided in the report of the research. If the drugs or medications used have any potency, they are bound to have some influence on the behavior and mental functioning of the subject studied. Not only must the taking of medication be clearly mentioned, but the medication used, the dosages, and in many cases, the duration of medication should also be specified. If part of a group of subjects is on medication and a part is not on medication, there are clearly problems in mixing the results of these two subgroups and treating them as one relatively homogeneous group. In a related fashion, comparing a clinical group of subjects receiving medication with a control group that is not must influence the kinds of conclusions that can be drawn from such comparisons. If one is attempting to compare the effects of drugs on two groups of comparable patients, then, of course, the previous comparison would be feasible, providing a placebo was used with the control group. However, if the comparison were made

to compare the mental functioning, behavior, or personality characteristics of a given diagnostic group with some other group, then such a comparison would provide results contaminated by the influence of the medication. Although this appears quite obvious, it is surprising how frequently this kind of a problem is ignored or glossed over in manuscripts submitted for publication.

Another problem concerns the lack of adequate information presented on the particular techniques or methods of appraisal used in the research study. This is of particular consequence when such procedures are not standardized ones, are not very well-known, or have been constructed by the investigators for their specific research, often without adequate reliability or validity studies. It is the responsibility of investigators to describe clearly the procedures and techniques that they have used in their study so that others can fully understand what has taken place and be able to attempt possible replications of the study if they so desire.

With the pressures for publication evident today and the corresponding desire to use journal space as efficaciously as possible, it is understandable that editors want manuscripts to be as brief and concise as possible. Unnecessary verbiage should, of course, be deleted from all manuscripts. Nevertheless, this does not mean that significant information about a research project should be omitted. When relatively unknown tests or rating scales are used, for example, the investigator should describe them in sufficient detail so that the reader has a clear understanding of the techniques used and can appraise their suitability for the sample used and the problem under investigation. The investigator should also provide pertinent data concerning the reliability and validity of the procedures used in these instances as well. Since the value of the results secured in any research study is dependent on the types of measures used, such information would appear to be essential.

The Lack of Cross-validation

One of the apparent causes of concern about much past and current research, not limited to clinical diagnosis alone, is the large num-

ber of conflicting findings in the literature and the apparent difficulty encountered in the replication of published findings. This has become such a regular feature of research in clinical psychology that many review articles tend to sum up the number of positive and negative studies on a given topic. If over half of the studies appear favorable to a given proposition, then that view is judged to have some support, even when the studies vary greatly in quality. This is a somewhat risky kind of approach to drawing conclusions about some technique or finding. If a particular treatment, for example, is found helpful in eight investigations and harmful in four, should it be concluded that the overall impression is that the treatment is helpful? The fact that there are such conflicting findings should make us suspect some possible limitations in the research reported and withhold judgment until we are able to explain the confused findings.

Most likely, the discrepancies among research reports are due to subject variables, small samples, and variations in diagnostic procedures, as well as to chance variables. Because of the kinds of problems already mentioned concerning variations in assigning clinical diagnoses, in subject samples, in the kinds of settings used, and sometimes also in the procedures used, the findings from any single investigation can only be viewed as suggestive. Although attempted replications by other investigators in different settings appear to be essential in appraising the value of any investigation, there is one procedure that most researchers could use to improve the reliability of their findings. This is simply to secure enough subjects in their experimental and control groups so that all groups could be randomly divided into two groups. The study is then conducted with one set of groups functioning as the initial group, and the second set can then be used for cross-validation. This is a relatively straightforward procedure that has been used in some studies, but relatively infrequently.

Examples of studies that contained such attempts at cross-validation and that also illustrate their value are Garfield and Wolpin (1963); Lorr, Katz, and Rubinstein (1958); and Sullivan, Miller, and Smelser (1958). In

the study by Sullivan et al., two cross-validations were carried out on MMPI profiles of patients who terminated prematurely from psychotherapy, and the results of the cross-validation attempts were clearly important in the final conclusions drawn. In this study, significant differences between premature terminators and those who continued in therapy were found for several MMPI scales for *each* of the several groups of subjects investigated. However, *none* of the scales that differentiated the groups under study showed a consistent pattern. For each separate appraisal different scales were found to be significant in their differentiation. Consequently, the findings secured in the first appraisal were not supported in the subsequent cross-validations, and the final conclusions reached were different than they would have been if the cross-validations had not been attempted. These authors, at the conclusion of their article, emphasized the necessity of cross-validation, and I strongly concur with their conclusion.

Although attempted replications or cross-validations by other investigators would also be required to fully evaluate the significance and utility of findings reported in a single investigation, the procedure suggested here is still a useful one for increasing the potential value of single studies. Most likely it might require larger initial samples of subjects so that the samples can be divided into two groups for purposes of cross-validation. However, such extra effort and cost would appear to be justified by the possible increase in the significance of the findings secured, and perhaps some premature generalizations and conclusions might be negated.

Because of the complexities and potential problems in conducting research in the area of clinical diagnosis, investigators in a majority of instances should attempt some sort of cross-validation before reaching conclusions and before submitting their research reports for publication. Their findings would tend to have greater reliability and validity, and, hopefully, the parade of contradictory findings that appear in our journals would be decreased. Initial findings of a single investigation that have not been cross-validated but that appear to be of possible importance should be submitted for publication only as

brief reports. As already mentioned, such findings that have not been cross-validated can only be viewed as suggestive.

Miscellaneous Issues

There are also several other issues that can be mentioned somewhat briefly. All investigators can be presumed to be aware of these matters, but at times there appear to be some lapses in attention to them.

One basic consideration that is sometimes neglected concerns the careful checking of results and computations before submitting a manuscript for publication. This seems so obvious as to not require any mention here, but errors in computation do occur. In the apparent haste to get the manuscript ready for submission for publication, an author may fail to detect some rather obvious, and at times important, errors in his or her manuscript. In some cases, the conclusion drawn from the study may have to be greatly modified, which is a decided embarrassment to the author involved.

Related to the above are occasional misuses of statistical procedures. In the case of chi-square, inflated *N*s, based on the number of observations instead of the number of subjects, can provide spurious results. The use of parametric statistics for nonparametric data is another example. One of the more common errors is treating highly related measures or ratings as independent measures. Because a number of us are deficient or not up-to-date on our knowledge of statistical procedures, it is a wise procedure to seek consultation from other more knowledgeable individuals when we are planning studies, when we are ready to analyze our data, and when we are interpreting and writing our research results.

Another matter that is occasionally noted pertains to the interpretation of findings secured by means of correlations. Coefficients of correlation are useful indices of the relationship between two variables. However, the relationship between two variables cannot be used as a basis for judging causality. For example, one may find a significantly high correlation between marital status and length of hospitalization. One might be able to say that marital status is a favorable prognostic in-

indicator for future discharge from the hospital, but one could not say that getting married causes a short stay in the hospital. It is conceivable that better integrated individuals or less asocial ones are more likely to get married and that these variables or others like them may possibly be related to outcome.

Another practice that I have occasionally noted is that of drawing major conclusions or inferences from very scanty or minor bits of data. One should not let his or her enthusiasm exceed the quantity and quality of the actual data secured. In one of the studies mentioned earlier, for example, in which a mean difference of .4 on a subtest of the WAIS was secured between two different administrations of the test, the author offered some detailed (and speculative) reasons to account for this "significant" result. Results of such magnitude do not appear to require any lengthy interpretations of the data.

Clinical Diagnosis: Some Concluding Comments

Because the issue of clinical diagnosis is such a complex, controversial, and yet crucial issue, a few final words on this topic are in order. It is readily apparent that any research on diagnostic groups, for example, schizophrenia or manic-depressive psychosis, can be no better than the validity or meaningfulness of the diagnoses secured and used. This problem has plagued research in this area for many years. On the one hand, systematic and reliable classification of subjects facilitates research and the accumulation of potentially meaningful data about types of psychopathology. On the other hand, if the classification scheme used for such research is beset with problems of clarity, reliability, and validity, the results based on such classification are bound to be limited in their usefulness. An unreliable and loose scheme is bound to produce unreliable and variable results. The most highly quantified data and the most exacting statistical analyses cannot provide worthwhile conclusions if the assumptions or foundation on which they are based are weak.

If research based on clinical diagnosis is to have any theoretical or clinical value, more

attention will have to be paid to improving the selection and specification of research samples. Otherwise, we will continue to have the confusing array of conflicting and contradictory findings that makes its way into the published literature each year, despite the high rejection rate of journals published by the American Psychological Association.

Although it will not be easy to improve the situation greatly, it is my belief that some improvements can be made in the current situation. Editors should openly state that articles based on broad diagnostic categories will usually not be accepted for publication. That is, reports on "schizophrenia," "brain damage," and the like, will be considered too diffuse to merit publication. Instead, greater specificity will be required in the future. In line with the suggestions discussed earlier in this article, the authors of studies will be expected to specify and describe their research subjects in ways that give more meaning to the diagnostic categories studied. In cases diagnosed as schizophrenic, for example, the patients will have to be described also in terms of measures such as process-reactive; good or poor premorbid; the MMPI; IQ; factored scales such as those developed by Lorr, Klett, McNair, and Lasky (1962); and the like. Major symptoms of the subjects should also be described and rated on reliable scales. To treat schizophrenia as a single meaningful category or disorder is to court chaos and disaster.

In a similar manner, brain damage has for too long been treated as if it were a unitary disorder when actually a great variety of disorders and impairments have been subsumed under this crude designation. The site of the disorder in the brain, the type of lesion, the type of onset, and the source of the disorder or injury are all pertinent. Even though some progress in the direction suggested here has been made in recent years, much more needs to be done along these lines. This is particularly true as new and equally vague categories such as the hyperactive child, minimal brain damage, infantile autism, and learning disorders begin to receive both popular and research attention.

Unless we pay attention to the research issues involved and try for as much specifica-

tion as possible of the disorders we are studying, our research efforts will only produce conflicting and disappointing results, and clinical practice will be the loser. We can learn from our past deficiencies and, hopefully, strive to improve the quality of our investigative efforts.

Methodological Considerations in Clinical Neuropsychological Research

Oscar A. Parsons and George P. Prigatano
Department of Psychiatry and Behavioral Sciences
University of Oklahoma Health Sciences Center

Methodological problems and issues in clinical neuropsychological research are discussed for four types of neuropsychological studies: (a) differential diagnosis, (b) basic brain-behavior relationships, (c) effects of noxious agents or factors on brain-behavior relationships, and (d) rehabilitation of neuropsychological deficits. Recommendations as to how to handle these methodological problems are made. The characteristics of good case study reports are presented.

Neuropsychology is the study of brain-behavior relationships; clinical neuropsychology is the application of empirically established facts concerning these relationships, and theories derived from them, to clinical problems. During the last decade we have witnessed an outpouring of research in clinical neuropsychology. All indications point to a continuation of this healthy and vigorous area of research. In this article we discuss some of the methodological problems that, if carefully considered and acted on, could substantially improve the quality of the research. (And we include ourselves as recipients of that admonition!) In some instances the methodological points made will have much in common with any psychological experiment; in other instances problems that are fairly unique to neuropsychological research will be addressed.

Before consideration of specific methodological problems, it is appropriate to point

out that competent clinical neuropsychological research demands mastery of several areas. The traditional areas of measurement of human behavior (psychometrics) and psychopathology, coupled with a serious study of the central nervous system (e.g., neuroanatomy, neurophysiology, and neuropathology) and exposure to clinical neurological concepts and procedures, are necessary, in our opinion, for the level of sophistication demanded by this complex field. This is not to say that one cannot conduct meaningful neuropsychological research without knowing the microscopic anatomy of the brain; we are saying that good neuropsychological research demands a background often lacking in psychologists' training. This is a remediable condition.

Given an adequate background, a second factor conducive to good research in this area is the continual recognition that behavior is the final common expression of a tremendous number of possible factors. We emphasize this somewhat trite and elementary maxim because it is seemingly frequently ignored. For example, cognitive "deficits" are characteristically found in brain-damaged patients, but they are also present in patients with schizophrenia (G. Goldstein & Halperin, 1977), depression (Miller, 1975), anxiety (Chapman & Wolff, 1959), or culturally deprived or educationally disadvantaged persons (Amante, VanHouten, Grieve, Bader, & Margules, 1977). In the Halstead-Reitan Battery (Reitan & Davison, 1974), much attention is

Preparation of this article was supported in part by U.S. Public Health Service, National Institute for Alcohol Abuse and Alcoholism Grant AA 01464 to the first author.

George Prigatano is a visiting scholar at the Department of Psychology, Stanford University, Palo Alto, California.

given to differential left-hand and right-hand motor performance as an indication of laterality of cortical damage. However, poor motor performance with either hand may result from peripheral motor and sensory injury of a subtle nature. Unless this possibility is thoroughly explored by careful history taking, erroneous inferences could be made about the brain state. Our point here is that if the neuropsychological researcher keeps this maxim in mind, possible alternative explanations or confounding variables may be anticipated, thus resulting in a more acceptable research report.

Let us consider, for example, five independent variables that most experimenters would agree are of importance in behavioral research: age, education, sex, socioeconomic level of subjects, and experimenter or examiner characteristics. Are these variables also important in neuropsychological research?

Age

Heaton, Baade, and Johnson (1978) have recently reviewed 94 studies in which neuropsychological test scores of psychiatric patients and brain-damaged patients were compared. In 38% of these studies, age was either not mentioned or the groups differed with respect to age. Given the well-known relationship of age to cognitive, perceptual, sensory and perceptual-motor, and information-processing variables, most of which are being measured in neuropsychological studies, it is vital that age receive close scrutiny. The safest procedure is to equate groups being studied on age both as to means and standard deviations. If age is significantly different for groups, and age matching by dropping or adding subjects is not possible, there are several alternatives. First, it should be determined if the dependent variable is in fact correlated with age. If it is not correlated in the brain-damaged, control, or other experimental groups, then it is likely that age could be discounted as a significant factor.

Note, however, that a lack of correlation in the brain-damaged group could not be used to disregard the influence of age. Heterogeneity of damage to the brain could obfuscate any general relationship. For example, Prigatano and Parsons (1976), in a cross-validated

study, found that the Category and Tactual Performance Test measures on the Halstead-Reitan Battery correlated significantly with age in both brain-damaged and non-brain-damaged groups but that the Rhythm, Speech Perception, and Tapping tests correlated significantly only in the non-brain-damaged groups. Apparently, the brain-damage effect was sufficient to override the effects of age in the latter variable. Incidentally, the correlations of age with the Halstead Impairment Index in the non-brain-damaged groups were .57 and .64; in the brain-damaged group they were, respectively, .33 and .44. All correlations were significant, but they were consistently lower in the brain-damaged group.

Another method of handling age difference among groups, once the relationship between age and dependent variables has been established, is to adjust the dependent variable scores by analysis of covariance and then test for differences. Partial correlational techniques could also be used. To repeat, however, the most clear-cut solution is to equate groups on age means and variability.

Education

Heaton et al. (1978) were "reassured" by the 60% of the studies that they reviewed, which stated that the groups under investigation had comparable educational background. What about the 40% who did not? Does education make a difference? Two recent articles have addressed this question. Prigatano and Parsons (1976) correlated education and Halstead Battery performances in brain-damaged and other patient groups. Neither the brain-damaged nor the psychiatric group had significant correlations. However, in a group of non-brain-damaged general medical-surgical patients ($N = 50$), they found significant correlations with six Halstead measures. It seems likely that psychiatric disorder and brain damage introduce enough variance to reduce the correlation found in a nonpsychopathological population. The effects of education were demonstrated in a clear-cut fashion in a recent study by Finlayson, Johnson, and Reitan (1977). These investigators compared brain-damaged and control subjects, stratified in three levels

of education, on the Halstead Neuropsychological Battery. Both level of education and brain damage had a "pronounced effect" on scores; the lower education groups scored lower on the Halstead measures, as, of course, did the brain-damaged group. Our recommendations to investigators as regards the possible effects of education are the same as we discussed for age.

Sex

Given the popularity of this variable in most dimensions of our lives, it seems rather strange that the possible differences between males and females in neuropsychological studies has received little attention. In fact, in the Heaton et al. (1978) article, sex is not even mentioned, let alone introduced as an important methodological variable! Yet there have been at least two neuropsychological studies that have found that the sex variable is of some importance. Lansdell (1968) studied male and female epileptic patients who had temporal lobe tissue removed. Difference in interactions of hemisphere and sex on perceptual variables suggested that subtle differences may exist in male and female brains as regards such variables. McGilone and Kertesz (1973) concluded that brain damage in males leads to greater functional asymmetry, especially in visual-spatial analysis (Block Design), than in females. In children, Witelson (1976) has demonstrated clear-cut male-female differences in tactile-spatial performance, with right-hemisphere-governed performance significantly better in males than in females.

Our suggestion as regards this variable is that when possible, groups should be equated on number of males and females; if this is not possible, then sufficient numbers of either ~~male~~ or females should be included to analyze the data for at least ~~one~~ sex with a respectable *N*. If small numbers of either sex are included in the total *N*, it should be demonstrated that obtained differences in dependent variables are similar to those effects obtained with the different-sex larger *N*.

Socioeconomic Level

This variable is closely related to education, and so in most adult studies, education is

sufficient. However, as education levels continue to rise and "social" promotions are the rule rather than the exception, it may be important to again consider the broader variable of socioeconomic level. Another aspect is the occupation of the subjects. Has there been overlearning of specific skills, which in turn could lead to spurious results? For example, manual workers and bookkeeper clerks might well differ in patterns of strength in perceptual-motor and verbal-calculation skills. Depending on the title of occupational representation in a given sample of brain-damaged patients, many different inferences can be made. The socioeconomic variable is quite important in neuropsychological investigations of children. Indeed, in a recent study, Amante et al. (1977) concluded that levels of neurological integrity vary along a socioeconomic gradient. The relevant factors associated with social causation include malnutrition, reduced environmental stimulation, and inadequate obstetrical and pediatric care.

We recommend that adult studies in neuropsychology consider the occupational variable along with education. Certainly with children, the general family socioeconomic background should be specified, as educational levels will be roughly equivalent for groups through age 16.

Examiner Characteristics

Another independent variable to be considered is that of the experimenter, or more specifically the examiner or tester. Schafer (1954) some years ago eloquently described the various problems faced by the psychological test examiner. Among them was the "pressure" to obtain a "score," a pressure that can often lead to an inattention to the patient's interpersonal needs during the examination or even to poor test administration. Inexperienced or poorly trained examiners making such mistakes may well fail to elicit maximum effort or motivation on the part of the patient. Without the latter, the validity of tests such as the Halstead-Reitan Battery may be questioned (Reitan, Note 1). Studies in clinical neuropsychology seldom describe the degree of expertise of the examiners. Certainly there are varying degrees of sophistica-

tion of the neuropsychology technicians used in the various clinical and research laboratories throughout the country. Yet, clinical neuropsychological research is often published with no mention of how this variable may have influenced their reported findings.

The social psychological research of Rosenthal (1968) has certainly pointed to the possible impact that experimenter or examiner expectations may have on subjects' performance or the evaluation of subjects' performance. Schachter (1964) has argued effectively that the perceived emotional environment can have a major influence on a person's subjective emotional state and reactions, which in turn can affect performance. Although there are relatively few neuropsychological studies that address these questions, Parsons and Stewart (1966) found that brain-damaged patients showed less improvement on a perceptual-motor neuropsychological test when examined by a "disinterested-factual" examiner as compared to one who was "supportive" and interested in reducing the patient's test anxiety.

The demonstration that the interpersonal climate is important in examining brain-damaged patients is important in view of the growing use of technicians and computer-run laboratories. A disinterested examiner or an interaction with a computer might create the type of atmosphere that interferes with the maximum level of performance in some patients or groups of patients but not in others, leading to conflicting results across laboratories.

We recommend that neuropsychological research reports state the level of sophistication and training of the persons who conduct the examination. A short description of the interpersonal climate would also be helpful (e.g., "patients were encouraged frequently"; "if tired, patients took a short break"; "instructions were given clearly, and testing did not proceed until the patient demonstrated understanding"; "supportive reassurance was appropriately given"; etc.).

Approaches to Neuropsychological Investigations

Neuropsychological studies customarily have fallen into three major types. In the

first type, the objective is the differential diagnosis of brain-damaged patients from non-brain-damaged control and other psychopathological groups, an applied or clinical problem. The second type seeks to identify and describe the general and specific changes in brain-behavior relationships as a function of brain states. The intent of these latter studies is usually to contribute to our basic understanding of neuropsychological relationships. The third type consists of studies that attempt to ascertain the effects of certain noxious agents (e.g., metabolic disease, drugs, trauma, etc.) on the brain-behavior relationships. Looming on the horizon, however, is a fourth type of studies, the new and challenging field of rehabilitation of neuropsychological deficit behavior. Of course, there are many studies in which several objectives are present, but for our present purposes we will consider the four types separately. Finally, we shall present our notions of what constitutes a good case study.

Differential Diagnosis

A problem area that has preoccupied psychologists since the rise of clinical psychology in the late 1940s is that of identification of brain-damaged patients. The objective of these studies is to develop behavioral measures that will discriminate a group of patients typically identified as "brain damaged" from patients who have another psychopathological disturbance (e.g., schizophrenia, depression, or anxiety) and from non-brain-damaged, nonemotionally disturbed control subjects. Although there are many investigators who have wondered whether continued efforts in this area are warranted (Parsons, 1970; Smith, 1975; Spreen & Benton, 1965), the continued interest and vigorous pursuit of such studies suggest that the working clinicians believe otherwise.

Subject Characteristics

The primary methodological problem is that of subject selection and subject characteristics. Let us consider the brain-damaged patients. It is not unusual in neuropsychological studies to find that the patients were de-

clared "clearly brain damaged" from the medical records by unknown or at least unidentified physicians or other persons (Heaton et al., 1978). There seems to be an assumption that perfectly reliable criteria were used. It should come as no surprise, however, to learn that even neurologists do not always agree on diagnosis of brain damage. In one of the classic studies (Fisher & Gonda, 1955), two skilled neurologists made a judgment as to whether damage existed rostral to the foramen magnum in patients who were given thorough neurological and other biomedical tests. This judgment was based on review of the records and included clinic follow-up reports and occasional autopsy reports. The agreement was 86% under these superior diagnostic conditions. Surely under less favorable conditions the percentage of agreement would drop.

Given the problems of cost, availability, and time, the preferred method of having two neurologists independently examine the patient probably cannot be achieved by most neuropsychological researchers. One solution would be to have at least one neurologist review all available data. Criteria of positive neurological examination plus at least one positive biomedical test (e.g., computerized axial tomography [CAT] scan, skull films, arteriogram, pneumoencephalogram, electroencephalogram, and so forth) could be used. A selected sample could be blindly rated again by the neurologist to give some indication of the reliability of his or her own diagnostic statements. The point is that more attention must be given to the defining criteria of brain damage, especially the qualifications and reliability of the clinical judges, the latter being preferably the relevant medical specialists (Jacobs, 1977). After all, the behavioral measures can only be as effective in diagnostic statements as the reliability and validity of the criterion measure of brain damage permit.

As Piotrowski (1940) pointed out almost 3 decades ago, one of the best ways to determine the diagnostic utility of neuropsychological tests would be to apply the tests to a sample of persons referred for suspected brain damage. Some of these people would show brain damage; others would not, the latter

constituting what has more recently been termed *pseudo-neurologic* (Matthews, Shaw & Kløve, 1966). If the neuropsychological tests (independent of the diagnostic process) can distinguish brain-damaged from non-brain-damaged persons, the tests have a diagnostic potential. Note that this is a more exacting procedure than the method mentioned earlier (i.e., using clearly diagnosed patients) and much more difficult to achieve practically. As neuropsychological testing has become more widespread and of demonstrated effectiveness (Filskov & Goldstein, 1974; G. Goldstein, 1974; Reitan & Davison, 1974; Satz, Fennell, & Reilly, 1970; Smith, 1975), it undoubtedly influences decisions about diagnoses. In retrospect these influences are quite difficult to partial out. Further, a non-invasive superior biomedical test, the CAT scan, is now in use at most centers. Patients who previously presented diagnostic problems, because of the physicians' understandable reluctance to use invasive techniques, are now diagnosed earlier in the process. Parenthetically, use of the CAT scan as an important criterion measure in neuropsychological studies will be routine in the future. It is important to note, however, that reliability studies of CAT scans are only now appearing and that normal values and ranges for given laboratories are frequently inadequate. At the present time, users of the CAT scan in neuropsychological studies would be advised to quantify their measurements as much as possible and to present interrater reliabilities.

Base Rates

To return to the problem of subject characteristics in studies of differential diagnosis, the ultimate criterion of a good diagnostic test is the "hit rate." The more true positives (brain damaged) and true negatives (non brain damaged) and the less false positives (not brain damaged called brain damaged) and false negatives (brain damaged called non brain damaged), the better the test. However, interpretation of the efficacy of hit rates is highly dependent on the base rates in the populations sampled. Contrast, for example, the high incidence of brain-damaged patients on the neurology service with the typically

low incidence seen on psychiatric services in general hospitals. The cost efficiency of neuropsychological tests (Rimm, 1963) will differ under these conditions. Clinical neuropsychological researchers should be thoroughly familiar with the base-rate problem (Gordon, 1977; Heaton et al., 1978; Krug, 1971; Rimm, 1963; Satz, 1966).

Test Variables

What should guide the researcher in test selection in studies of differential diagnosis? First, researchers should be aware of the studies that have compared hit rates with single and multiple tests. Spreen and Benton (1965), in their review, reported that individual neuropsychological tests discriminated brain-damaged from normal controls with an average hit rate of 71%; with several tests the cumulative predictive value was 80%. They concluded that the search for screening devices had reached its culmination point and served its purpose. Heaton et al. (1978) reported a median hit rate of 75% for 84 classification attempts involving a variety of psychiatric disorders but omitting process or chronic schizophrenia. Single tests and combinations of tests appear to have similar hit rates. The Halstead Impairment Index, an index based on seven tests, frequently gives the same level of hit rate as individual component tests (Smith, 1975).

In other words, for differential diagnosis there seems little warrant for constructing a large battery of tests. This is not to say that a large sampling of test behaviors is not important, rather it means that to answer the specific question of differential diagnosis, most good single tests give practically the same level of discrimination as combinations of tests. Of course, for gaining information, beyond that of diagnosis per se, enlarging the range of behaviors studied (i.e., multiple tests) is highly desirable. In fact, in most clinical settings, the emphasis today is on specifying the nature and location of the brain damage. As the field moves toward a greater emphasis on rehabilitation, as we will discuss later, a more extensive sampling of behavior may be required.

Reliability of tests is always a concern for

the researcher. What do we know about the reliability of neuropsychological tests? Matarazzo, Matarazzo, Wiens, and Gallo (1976) presented test-retest data on the Halstead-Reitan Impairment Index for four groups of subjects: normals, schizophrenics, and two samples of organic patients. In the patient groups the test-retest reliability was reassuringly high (.83, .63, and .82), considering that test-retests in clinical populations are always attenuated by change in patients' conditions over time. In the normals it was low (.08), but this was due to the latter's extremely low Impairment Index scores; actually 29 out of 29 were classified as normal in each testing, for 100% accuracy. Of course, if the investigator is devising a new test, test-retest reliability coefficients should be presented. If for some reason this is not possible, other estimates of reliability such as split-half correlations can be used. As we will discuss later, reliability of the test is significant in specification of group difference in performance. We are past the day when investigators try out a new test in brain-damaged and control groups, find large differences, and optimistically submit the results for publication without considering such basics as reliability.

Statistical Analysis

In recent years the advent of computer analyses has enabled multivariate statistics to be applied to problems in differential diagnoses. These analyses have the advantage of maximizing differences among groups and identifying the measures on which groups differ most (G. Goldstein & Halperin, 1977; Swiercinsky & Warnock, 1977). It should be recognized that the sensitivity of multivariate analyses in accentuating group differences capitalizes on the chance variance that may be present as much as on true variance differences. Any study that purports to have heightened discrimination through multivariate analysis should be cross-validated. For example, in discussion of the use of stepwise regression multivariate analysis, Cohen and Cohen (1975) advise that if the results are "to be substantively interpreted, a cross-validation of the stepwise analysis in a new sample be undertaken, and only those conclusions

which hold for both samples should be drawn" (p. 104).

In our opinion the search for the Holy Grail (i.e., the neuropsychological test(s) that will give a high discrimination of brain-damaged patients from controls or other psychopathological groups in all types of settings, with all socioeconomic levels) is not likely to be as productive as other research approaches. If one feels compelled to continue this search, then we suggest that the investigator follow these basic suggestions: (a) Give specific information on the reliability of the diagnoses (done preferably by relevant specialists) for all of the patient groups studied; (b) give some estimate of the base rate of brain damage in the samples studied and compare hit rates with them; (c) give some indication of the reliability of the tests used for measurement; and (d) conduct a cross-validation study to determine whether the statistically maximized hit rates will hold for another sample.

Studies Elucidating Basic Brain-Behavior Relationships

In these studies the concern is with gaining basic understanding of the qualitative differences in brain-behavior relationships. What are the functions of the right and left hemispheres? Are there different behavioral patterns characteristic of localized lesions? These and many other questions are answered by studying patients who are identified on the basis of known damage to the brain in certain areas (e.g., left-hemisphere lesion vs. right-hemisphere lesion patients). The patients are given neuropsychological tests and, if differential results are obtained, inferences are made about the role of those affected neuro-anatomical regions in behavior.

General Versus Specific Effects

At the outset it is important to recognize that there are both general and specific effects of brain damage (Adams, 1969; Chapman & Wolff, 1959; Parsons, 1970; Smith, 1975) and that both effects are dependent on the size or extent of the lesion. Chapman and Wolff (1959), in a classic article that should

be read and reread by researchers in clinical neuropsychology, have provided convincing evidence of the relationship; the larger the amount of tissue removed from the brain, the greater the postoperative impairment of the patient. Specific effects on neuropsychological tests will always be embedded in the larger context of these general effects; comparisons of different lesion locations should be made with patients who have roughly equivalent amounts of dysfunctional or destroyed tissue. If patients are being compared who have not had neurosurgical intervention, this may be a difficult condition to meet. However, some estimate could be made by neurologists' ratings of severity of the effects of the damage (Parsons, Vega, & Burn, 1969).

Variables Related to the Changed Brain

There are a number of aspects of the lesion or disease process to be considered. One variable of utmost importance is duration of the lesion or time since insult to the brain. Smith (1975) provided a clear discussion on the effects of diaschisis (i.e., the effects of localized lesions on more distant parts of the brain). He cited studies indicating disturbed cerebral hemisphere blood flow and cerebral metabolism in both the diseased and healthy hemispheres of patients. Diaschisis is related to the "general" effects noted above but may be separable in that it contributes to the general effects in the period immediately following the insult but diminishes in effect over time.

Another aspect of the duration of lesion variable is the age at which the insult occurs. It is well-known that effects of brain damage as measured in adulthood are dependent on whether the damage was incurred as a child, while the brain was still developing, or after physical maturity of the brain has been reached, that is, by age 15 or 16. (See various chapters in Reitan & Davison, 1974.) Even in adulthood it would appear that duration of several years is a critical value. Over time, static lesions lead to less discriminating differences than lesions that are relatively acute (Reitan, 1966, 1974). Rapidly growing or worsening lesions are also likely to lead to much greater deficits than static lesions even

if the duration is equivalent (Fitzhugh, Fitzhugh, & Reitan, 1961; Reitan, 1966). Combining brain-damaged subjects who may differ in terms of age of onset, time since insult, static or changing nature of lesion introduces diverse sources of variance. Either inaccurate attenuation or accentuation of specific brain-behavior relationships could occur.

The nature of the disease process or dysfunctional brain state is important. Reitan (1966, 1974) has pointed out that cerebrovascular disease, neoplasms, trauma, and degenerative diseases give rise to different patterns of neuropsychological deficits. Different percentages of such patients in any specific localization studies could give rise to misleading generalizations of conclusions regarding specific brain-behavior relationships.

Handedness, Aphasia, Visual Field Defects, Emotional Responses

Four other subject variables deserve noting: handedness, presence of aphasia or visual field defects, and the patients' emotional responses. It is customary to specify the handedness of the population being studied. (Eyedness and footedness are also frequently noted, but their relationship to performance is less clear.) The difference in lateralization effects as a function of handedness is currently the subject of many investigations (See any recent issues of *Cortex* and *Neuropsychologia*.) The relationship is complex and not at all clearly understood, but one conclusion is obvious: Groups to be compared should be composed of similar percentages of right-handed and left-handed subjects.

The presence of aphasia is important in studies of lateralization or localization. Disturbed language functioning may grossly affect the understanding of oral or written instructions or the communications of answers to questions or both (Zangwill, 1969). Inferences made about disturbed, nonverbal, higher cortical functioning in such patients may be incorrectly made. It is of importance to identify the aphasic subjects and the nature of the aphasic disturbances in studies of general effects of brain damage (in which estimates are made of overall levels of intellectual functioning), as well as in lateralization or localiza-

tion studies. A similar caveat can be made for visual perceptual studies in which patients with visual field deficits are used. Faglioni, Scotti, and Spinnler (1969) have presented convincing evidence of the clarification of research findings by considering this variable.

Finally, we should consider the role of the patient's reaction to his or her changed brain state. Parsons (1970) has discussed this issue rather thoroughly, as have other workers (Chapman & Wolff, 1959; K. Goldstein, 1959; Reitan & Davison, 1974; Smith, 1975). Although the typical emotional response of brain-damaged patients to their condition is depression (Parsons, 1970), there are a variety of other effects as described by Chapman and Wolff (1959), including emotional and physical withdrawal, circumscribed interests, increase in premorbid defenses, and lowered frustration tolerance. Kurt Goldstein's (1959) discussion of the organismic changes of the brain-damaged patient places this problem in an even broader holistic framework. Complicating the picture, however, is the recent evidence (Galín, 1974), which suggests that left and right hemispheres may be differentially salient in the control of dysphoric and depressive versus euphoric and sense of well-being feeling states.

In studies that attempt to uncover basic brain-behavior relationships, care should be taken to distinguish general from specific effects. Unless controlled or otherwise accounted for, a number of variables can influence the results and hence the interpretation of specific brain-behavior findings. These variables include age at which the damage occurred, time since onset of lesion, static versus changing (worsening) condition, type of disease or injury, handedness, presence of aphasia and visual-field deficits, and the patient's emotional responses. We suggest that these variables be assessed or otherwise noted in research reports.

Studies of the Effects of Noxious Agents or Factors on the Brain

In this class of studies, the experimenter is usually concerned with the question, what is the effect of "X" (e.g., anoxia, hypoglycemia, LSD, alcohol, liver disease, periods of uncon-

sciousness from trauma, penetrating head wounds, unilateral electroconvulsive therapy, etc.) on functioning of the brain? Whether the variable is an acute study, such as acute alcohol ingestion, or a chronic study as in the neuropsychological changes in chronic alcoholics, the intent of these studies is usually to specify the brain-behavior relationships affected so that appropriate prevention and remediation techniques could be used. Both general and specific effects are likely to be investigated. Most if not all of the methodological variables previously described are pertinent here. Among the specific effects, a popular current line of research is the differential effects of various agents on hemispheric laterality of function. Parsons (1975), for example, has suggested that both the acute and chronic effects of alcohol are more detectable in behaviors associated with right-hemisphere saliency as opposed to behaviors under control of the left hemisphere. If we are interested in whether variable X does result in differential hemispheric test performance, it is advantageous to have tests that differ in content (e.g., verbal and visual paired associates) but are of the same general level of reliability and item difficulty.

Chapman and Chapman (1975) have shown how the more reliable test will lead to the greatest differences among the groups. For example, if the verbal paired associates are of greater reliability than the visual paired associates, even though both might be depressed by variable X, the more reliable test will give rise to the greater and more significant differences. Further, they point out, item difficulty also helps determine the mean difference between groups on tests. Item difficulty affects task variance; the larger the task variance, the larger the separation of groups of high and low ability on the test.

In other words, to examine the effect of variable X on tests measuring right- and left-hemisphere functioning or other comparisons such as frontal versus postfrontal functioning, it would be highly desirable to use tests that are equivalent in reliability and item difficulty. The Wechsler Adult Intelligence Scale (WAIS) satisfies, at least in part, these requirements, which may be one of the reasons why the WAIS continues to be widely

used in neuropsychological research even though it was designed for a different purpose. Although we cannot hope to achieve the comparable psychometric status of the WAIS for most of our neuropsychological tests without national and federally supported effort, we believe that the kind of careful analysis of the psychometric properties of the tests (reliability and item difficulty) as advocated by Chapman and Chapman (1975) provides a rather clear direction for more sophisticated research in this area.

Rehabilitation of Patients with Neuropsychological Deficits and the Case Study Method

Clinical neuropsychologists are becoming more aware of their potential contribution to the field in identifying behavior changes following brain injury and developing rehabilitation programs to improve neuropsychological functioning (Diller, 1976; Lewinsohn, 1973; Diller et al., Note 2). Strategies for improving body image perception, adapting to visual field deficits (Diller et al., Note 2), and improving memory functioning (Lewinsohn, Danaher, & Kikel, 1977) have appeared, which provide excellent examples of what can be done when specific cognitive and perceptual retraining programs are attempted with brain-injured patients. Moreover, there is therapeutic value in providing specific information concerning the nature of a patient's deficits when consulting with patients, their families, and employers. A recent article by Fuld and Fisher (1977) makes this and other important points regarding the management of children with closed head injury. In general, the methodological problems in this area are similar to those discussed previously and will not be repeated. However, as in all cases of remediation, the major problem is identifying the factor(s) at work in change in behavior over time. Without adequate control groups it is difficult to describe causal effects due to the training procedures used. A second problem will be to develop repeatable techniques in which effects of practice can be distinguished from improvement. Our prediction is that this area will gradually become one of the major thrusts of neuropsychology.

Case Study Method

Although group studies in this area are certainly desirable, the time is ripe for the appearance of systematic individual case studies that report on the patterns of neuropsychological recovery following various brain injuries. (For an example of this, see Prigatano, Note 3.) Also, case studies that attempt to assess the efficacy of various treatment or rehabilitative efforts on improving rate and level of recovery are needed. The possible experimental designs that might be used in the single case study are described in detail by Barlow and Hersen (1973). A good example of how individual case studies can lead the way to more systematic group research is seen in the work of Lewinsohn and his associates. Lewinsohn et al. (Note 4) described in some detail a model for assessing memory deficits and their treatment in individual patients. Later, after several patients had been evaluated and treated, group analysis of the data was made, and some important points regarding the value of visual imagery in working with these patients was documented (Lewinsohn et al., 1977).

Also, the use of the case study method to convey the human struggle involved in the recovery process can be a powerful source of inspiration to other workers in the field. Luria's (1972) description of one man's lifetime determination to overcome neuropsychological deficits secondary to a left-temporal-parietal injury is an account that few readers will forget. It serves as an important reminder of what can be done when human will and ingenuity are combined.

Finally, the value of the case study method in making theoretical points is no better demonstrated in the famous case of H.M., in which Milner, Corkin, and Teuber (1968) have shown that specific long-lasting deficits in memory can take place with no concomitant impairment in other global cognitive functions (i.e., WAIS IQ scores). Other studies have also used the case study method to make important theoretical as well as practical clinical observations (e.g., Geschwind & Kaplan, 1962; Wechsler, 1977).

With this background, it may be of some value to review what goes into a methodologi-

cally sound case study and the advantages and disadvantages of this approach. A methodologically sound individual case study clearly defines why the in-depth analysis of a given patient's behavior is generally important to the field. Without this, it is simply an explication of behavior that may or may not have been seen by other investigators and adds little scientific knowledge. Next, the case study must present a clear statement of the patient's history, symptoms, and laboratory data to allow the reader to come to some conclusions about the patient's situation. If this cannot be agreed on, whatever point is being made by the case study will inevitably be obscured. Third, reliable and validated measures, repeated observations, and/or experimental designs devised for individual case studies (see Barlow & Hersen, 1973) should be used whenever possible. This allows the reader to objectively evaluate *data*, not clinical impressions, about a patient.

The advantages of the case study method are that it (a) provides a detailed look at several interacting variables, which is often impossible within the confines of group studies; (b) allows for the appraisal of clinical as opposed to the purely "statistical" significance of a phenomenon; (c) shows documentation of clinical material, which has theoretical importance; and (d) serves as a reminder to investigators that the field must eventually include some explanation of the individual's behavior. The disadvantages are (a) the potential unreliability of a single case and (b) the inability to quantify the effects of potentially relevant variables. With these considerations in mind, the use of the individual case study method can be a useful adjunctive method in the field of clinical neuropsychology. We hope to see more of such studies in the future.

Conclusion

Methodological problems in clinical neuropsychological research are similar in some respects to those encountered in all of behavioral research. Among these are subject variables such as age, education, sex and socioeconomic level, and experimenter characteristics, such as degree of training and attitude. Dif-

ferent types of neuropsychological investigations pose different methodological problems while sharing certain common concerns. Studies of differential diagnosis require attention to reliability of diagnosis, statements as to hit rates in relation to base rates, and reliability of tests. Cross-validation of new findings, especially if multivariate analyses are used, are almost mandatory. Studies that attempt to elucidate basic brain-behavior relationships should be concerned with distinguishing general from specific effects, amount of dysfunctional tissue, duration of lesion, age of onset, type of disorder, handedness, presence of aphasic or visual field defects, and the patients' emotional reaction. Investigations of the effects of noxious agents on brain function, especially differential effects that depend on different neuroanatomical regions, should contain tests of appropriate content (e.g., verbal vs. visuospatial) that are equivalent on item reliability and difficulty. The emergent field of rehabilitation of neuropsychological deficits will have a major problem in demonstrating that improvement in neuropsychological performance is due to the training and not to practice or recovery associated with passage of time.

Common Methodological Problems in MMPI Research

James N. Butcher and Auke Tellegen
University of Minnesota

Research with the Minnesota Multiphasic Personality Inventory (MMPI) continues at a high rate. Unfortunately, too many articles submitted and even accepted for publication are methodologically weak. In this article we discuss some common methodological problems involving the use of the MMPI, encountered in the course of reviewing articles submitted for publication. A number of relevant issues are discussed, and some suggestions for improving research designs are made.

Research with the Minnesota Multiphasic Personality Inventory (MMPI) has continued at a high level in recent years. As a self-report inventory that includes several measures of psychopathology, the MMPI, or some derivative of it, has become widely used as a descriptive instrument or a criterion measure in a vast array of clinical and research investigations. In 1972 Buros reported that over 200 books and articles on the MMPI are published annually. Dahlstrom, Welsh, and Dahlstrom (1975) cited over 6,000 references to the MMPI; Butcher and Pancheri (1976) reported over 600 recent references in cross-national MMPI research alone. Butcher and Owen (in press) recently reviewed and classified MMPI research for the past 5 years. As shown in Table 1, they found that over one fourth of the research was focused on two areas of "popular" investigation: alcohol and drug abuse, and crime and delinquency. Approximately 37% of the studies focused on the use of the MMPI to study nonpsychiatric populations—medical patients, parents, women, ethnic groups, college students, and the aged. The MMPI seems to have been widely accepted as a criterion measure of psychopathology by researchers who want to

measure psychological problems in a variety of nonpsychiatric groups. But studies pointing to the need for revision or modification of the MMPI are scarce. This absence of revision-oriented research is impressive, since the MMPI is around 40 years old and can be expected to show some signs of aging. The only serious efforts to modify the MMPI have been directed at shortening it: About 12% of the published research in the past 5 years concerned the development or use of shorter versions of the instrument.

There are many reasons for the extensive use of the MMPI: Its administration is relatively effortless; its scoring is objective; generally straightforward objective interpretive procedures are available; and its validity as a criterion measure is comparatively well founded. But some of the factors encouraging researchers to use a self-report personality measure such as the MMPI also result in the kinds of methodological flaws that this article may help to prevent. The MMPI is so easy to administer as a part of an ongoing study that researchers (even if they have little or no research background with the instrument) feel encouraged to include it. Furthermore, since good criteria in psychopathology or personality research are scarce, the MMPI scales are sometimes too readily adopted as expedient proximate criteria. (In some respects, one might almost consider the MMPI an "attractive nuisance" in the legal sense, to be approached with appropriate caution.)

The remainder of this article will focus on

We wish to thank David Lykken for commenting on an earlier version of this article.

some methodological problems that are often associated with research using the MMPI. We hope to provide some guidelines that could help avoid these difficulties, by providing minimal criteria. Some of these criteria emerged as a result of our experiences as reviewers of MMPI manuscripts that were submitted for publication in several psychological journals.

It will not be possible to provide an exhaustive review of all pertinent issues nor to avoid seeming at times somewhat dogmatic. Yet it is not our intention to "dictate" which areas of investigation are important or which ones should be avoided, or to impose idiosyncratic preferences for certain research methods when several defensible ones are available.

What Kind of Instrument is the MMPI?

The MMPI is often mistakenly considered to be an all-purpose personality assessment instrument that is sensitive to "normal range" personality attributes. Consequently, some researchers use the MMPI with groups for which a different instrument might be more appropriate. The standard clinical MMPI scales are measures of psychopathology, not general personality. The MMPI should not be made to do what it is not designed to do. Rather than use the MMPI inappropriately, it would be better to consider alternative or supplementary measures such as the California Psychological Inventory (CPI) or Personality Research Form, which focus on normal-range personality dimensions.

What kind of MMPI measures can or should be used? The eight clinical scales and the three validity scales plus *Mf* and *Si* are the best established and most widely used MMPI scales.¹ In view of the many problems that we have encountered in the computation of clinical scale scores, two suggestions are in order:

1. In research computations more understandable results will often be obtained if one does not use the *K* correction, but uses *K* as a separate indicator. This simply means that *K*'s validity as a "suppressor" is not assumed. Of course, appropriate multivariate analysis of one's data will permit determination whether *K* in fact does function as a suppressor in one's particular data set. The *K*

Table 1

Classification of Recent Minnesota Multiphasic Personality Inventory Research

Category	No. articles
Alcohol and drug abuse: detection and treatment	96
Short forms	66
Use with other tests or rating scales	62
Crime and delinquency	56
Diagnostic considerations: rules, profiles, and code types	50
Psychometric characteristics	49
Medical patients: physical disorders and symptoms	47
Correlation with diverse criteria	46
Women	42
Treatment variables and therapy outcome	38
Depression and suicide	38
College students and adolescents	34
Parents, couples, and families	33
Drug therapy: choice and effect	31
Race: cross-cultural, ethnic	31
Automated interpretation	26
Employment screening and job performance	24
Anxiety and stress	18
Brain damage	18
Sleep	10
Sexual deviation	9
Aging	5

score will often be found to be an additional measure of good adjustment rather than a measure of invalid variance. If non-*K*-corrected *T* scores are used, use the *correct* conversion tables. Occasionally manuscripts are received containing figures with non-*K*-corrected profiles drawn according to incorrect norms. Do not use the raw score indications printed on the standard profile sheet unless your scores are actually *K* corrected! If you are plotting non-*K*-corrected scores for Scales *Hs*, *Pd*, *Pt*, *Sc*, and *Ma* and plan to display these on the standard profile sheet, it is necessary to obtain the correct *T*-score elevation from a conversion table (e.g., in Dahlstrom, Welsh, & Dahlstrom, 1972) and draw the appropriate elevation from the *T*-score indica-

¹ Researchers interested in obtaining access to the item response data of the original Minnesota standardization sample should contact W. Grant Dahlstrom, Department of Psychology, University of North Carolina, Chapel Hill, North Carolina 27514.

tions on the side of the profile sheet. In spite of the above general recommendation about using non-*K*-corrected scores, it is sometimes useful for comparisons with other studies to do a parallel set of analyses using *K*-corrected scores.

2. Use raw scores in research computations rather than *T* scores unless the use of *T* scores is specifically indicated, for example, in the analysis of code types or when combining data from both sexes.

The eight clinical scales were developed primarily by means of empirical keying methods, using clinical diagnoses as criteria. Because of the primary reliance on external criteria rather than on internal structure, these scales are for the most part quite heterogeneous. Consequently, although these scales, particularly when used in combination, provide useful information as to the diagnostic status of a person (Dahlstrom et al., 1972; Overall, Note 1), they do not in any simple way reflect "what the patient is saying," that is, how the patient is *describing herself/himself* through the medium of the MMPI items. This, too, is important information. Nowadays we recognize more clearly than in the heyday of empirical keying and "dust bowl empiricism" that important and clinically relevant *direct* relations exist between the manifest content of a person's self-description and clinical symptomatology and behavior in general (e.g., Hase & Goldberg, 1967; Jackson, 1971; Koss & Butcher, 1973; Payne & Wiggins, 1972). In addition, in clinical use the client/patient's reply to MMPI questions, impersonal as the process may seem, is still a communication that he/she might expect the psychologist to receive. We therefore need to take steps to make this possible. Some organized way of "coding" the respondent's MMPI "message" is clearly called for. Two approaches are now open:

1. use of content homogeneous scales, including factor or cluster scales (Block, 1965; Eichman, 1962; Overall, Hunter, & Butcher, 1973; Stein, 1968; Welsh, 1956; Wiggins, 1969) and

2. use of so-called "critical items" (Grayson, 1951; Koss & Butcher, 1973; Koss, Butcher, & Hoffmann, 1976).

Both approaches can serve a very useful role complementary to that of the clinical scales.

Scale Proliferation

The development of additional MMPI scales has been a rather popular pastime for psychologists. There are presently more MMPI scales than there are items on the inventory! Unfortunately, much of the MMPI scale development does not derive from a sound conceptual framework. Many scales have been constructed by contrasting different "samples of convenience" (often of heterogeneous makeup or with important characteristics unknown). Often these scales are not cross-validated, and more often than not their psychometric properties and interrelations with other scales are not reported. Many new scales, since they are, after all, derived from the same item pool, prove to be largely redundant alternative versions of existing scales, although sometimes of poorer quality.

A researcher who is tempted to add to this plethora of scales would find his or her contribution to the MMPI literature better received and used if:

1. The investigator has very carefully considered the question of whether the MMPI item pool adequately covers the domain of content of the construct to be measured. If the answer is not affirmative, then the MMPI will obviously not serve the investigator's purpose very well, and the new scale will reflect more the characteristics of the MMPI item pool than the domain of the intended construct. We believe that this is in fact the case with some new MMPI scales.

2. The investigator can show the scale to be conceptually interesting.

3. The scale is developed and cross-validated on reasonably large, well-defined samples (whether it is an empirically keyed scale or one derived by internal consistency methods, e.g., factor analysis).

4. The internal structure of the scale is reported (internal consistency, possibly factor structure), and the relation to other MMPI scales is reported. These relations along with validity data would ideally reveal that the scale either is a superior alternative to an

existing MMPI scale or is a measure of a disposition or state not measured by existing scales.

5. In addition to publishing statistics on scale relationships, the author reports substantial external validation data. It is not sufficient to know that a scale correlates appreciably with a criterion, since, ideally, both convergent and discriminant validity information should be reported (Campbell & Fiske, 1959) for the new scale. It is also important to know how well a scale predicts behavior for the individual in various contexts. Thus some data reporting prediction success and failure in specific settings (e.g., in the form of hit-miss tables) are desirable.

New MMPI scales, like many of the old ones, should not be assumed to measure the characteristics suggested by its name or by its author. The researcher should be aware of the track record of a particular scale before he or she gambles on it. Block (1965) provided an interesting illustrative example:

However, ease of analysis should not mean casualness in regard to the scales chosen for study. On occasion, scales have been employed in circumstances which can only mean ignorance or naivete. These are harsh words but consider the following: several correlational studies in the response set domain have employed both the Prejudice (Pr) and Tolerance (To) scales of the MMPI. Both of these scales are due to Gough (1951; 1952). The Pr scale was developed and validated as an MMPI measure to correlate with the California Ethnocentrism-Fascism Scale (Adorno et al., 1950). Later, Gough decided to revise the Pr scale slightly and for entirely appropriate conceptual reasons took the occasion to relabel the scale as a measure of tolerance, reversing the direction of scoring of the items. In the To scale, 29 of the 30 items overlap with the Pr scale but scored oppositely.

Since the sample of scales selected for study can determine the shape of the results obtained, simple considerations of availability must be bolstered by actual knowledge of candidate scales. To use both the Pr and the To scales in the same study and draw faulty conclusions from their opposite but identical factor loadings is informative only about the investigators. (p. 118)

The MMPI wears other clothes as well. Many scales in the personality research domain have been generated from the MMPI item pool or from constructs so close to those covered by the MMPI that the items are virtually the same. Often the new researcher

is unaware of the original relationships or similarities and then conducts an "empirical" study rediscovering the affinity of the tests in question. A few instruments that are wholly or in part derived from the MMPI or are closely related are the CPI (over 200 items are common), the Taylor Manifest Anxiety Scale, and Lanyon's Psychological Screening Inventory.

MMPI Short Forms

A large number of recent studies have used one of the several MMPI short forms. It should be noted that the only MMPI short form recognized by the test authors and the publishers consists of a reduced number of items (around 400) that include *all* of the items required to score the 3 validity and 10 standard scales. The items excluded are those at the end of the booklet that are not scored on the basic scales. Some short forms have been the object of a large amount of recent MMPI work and have been developed by varying methods and for different purposes (the Mini-Mult, Midi-Mult, the Faschingbauer Abbreviated MMPI, MMPI-168, etc.)

Several recent studies have pointed out the limitations of MMPI short forms (Fillenbaum & Pfeiffer, 1976; Hedlund, Won Cho, & Powell, 1975; Hoffmann & Butcher, 1975). Although MMPI short forms may correlate significantly with the full MMPI, the resulting code-type congruence (hit rate) between the two forms is quite low (from 33% to 49%), too low to result in very similar individual clinical decisions. Although these studies indicate the need for caution in not accepting short forms at face value as adequate substitutions for full-length MMPI measures, many investigators continue to consider an MMPI short form as a near-equivalent set of scales. It is conceivable that some short forms could serve in a much more limited way as measures of global psychopathology.

How to Find Relationships: Problems in Discovering and Appraising Relations Between the MMPI and Other Variables

All MMPI research can be viewed as essentially correlational research, whether the

MMPI scales are the "dependent" or "independent" variables and whether we compute correlations explicitly or, for example, do *t* tests, comparing one group with another on certain MMPI measures (e.g., patients vs. normals), or determine hit rates obtained with certain MMPI-based diagnostic rules. Sometimes the *strength* of the relation investigated is immediately given by our statistics (e.g., correlation coefficient, hit rate), sometimes it is not (*t* test, *F* ratio). It is known but easily forgotten that some measure of strength of relation is *always* necessary if we are to determine the importance of our findings. Demonstrating statistical significance is necessary, but it is not enough. Not only should the magnitude of, for example, a correlation coefficient be considered but also its confidence interval. Yet one suspects that an inverse relation exists between the sample sizes used in published studies and the strength of the relations that are claimed to exist between certain variables. The reason, of course, is that a good way of "discovering" dramatically strong relationships in a set of data is to collect several measures, preferably those that can be expected to show *some* moderate interrelations, using a small sample. Chance alone will move a few of these expectable relations up into the "strikingly high" range (the "trade-off" being that one can expect to "lose" some of the other relationships by fluctuations in the opposite direction).

In short, sample sizes should be large enough to permit conclusions about the *strength* of the relationships under consideration that go beyond the inference that the null hypothesis is false. The rejection of this null hypothesis is a trivial contribution, particularly if the observed relationship is in the (more or less) expected direction, because, as has been pointed out, we practically *know* the null hypothesis to be false—almost everything is somewhat related to everything (Lykken, 1968; Meehl, 1967). *Example:* Suppose one collects data on a (small) sample of 19 subjects and "discovers" a somewhat unexpected correlation of .50 between Scale 7 and a psychophysiological measure of "arousal," skin conductance level. The corresponding *z* value of .50 is .55 with a standard error of .25.

The .05 (two-tailed) confidence interval for this correlation, then, in *z* values, is $.55 \pm .49$. In correlational values the corresponding range is between .06 and .78. The finding of a possibly very weak correlation, one that is only significantly greater than .06, we submit, is hardly a contribution (particularly not in this case, since the direction of the relation was more or less anticipated), in spite of its statistical significance and observed magnitude. Large sample sizes are essential to achieve less trivial results. Admittedly, if an observed relation is definitely not in the expected direction, and is definitely "significant" (even though the estimate of its strength still has a large margin of error), and involves a truly interesting relationship, then we might speak of a finding that deserves publication at this point to stimulate further research in what now appears to be a promising area. Nevertheless, it would still be better to follow up one's own findings with a replication permitting a more precise estimate and demonstrating a relationship of nontrivial strength. (After all, the more interesting our findings are to us, the less expected they must have been, and therefore the less reason we apparently have to assume their replicability without further test!)

One fairly common practice is to calculate multiple correlations, often on a small sample, and to announce their statistical significance without reminding the reader that the magnitude of the obtained multiple correlations may be substantially inflated. Without cross-validation or an appropriate "shrinkage" estimate, this procedure can be grossly misleading. (See Schmitt, Coyle, & Rauschenberger, 1977, for a recent discussion of this topic.)

Almost *all* MMPI research is multivariate (whether or not multivariate statistics are actually used). This, in combination with the frequent availability of "samples of convenience" (consisting, e.g., of individuals who have completed the MMPI as part of a screening procedure in some clinical or counseling setting), inevitably invites "look-see" or "shotgun" studies, guided only by the investigator's vague hope of finding something somewhere among the many possible relations that might be subjected to scrutiny. Particularly if the sample is small, chance findings

will often occur, and if one's sample of convenience is, in addition, poorly defined, then even nonchance findings may well prove not replicable in the absence of clear understanding of to what population the results are to be generalized. Unfortunately, a rather large number of manuscripts describing "one shot" studies using small and haphazardly collected samples continue to be submitted for publication—and to appear in print.

Another undesirable practice is to boost sample sizes by lumping together subjects differing on some potentially important characteristics such as sex, age, race, and socioeconomic status (Carlson, 1971). Sometimes these variables may in fact prove not to be important for the relations of interest to the investigator. But this cannot be assumed. At the very least sex ought to be included among one's variables. However, this would still not allow for the possibility that relationships between the MMPI and other variables, for example, response to treatment or diagnostic status, might differ for the two sexes, for different age groups, and so on. If sample sizes permit, the simplest first step would be to subdivide one's sample into relatively homogeneous subgroups in respect to major differentiators (sex, age, and so forth) and to evaluate the relationships in the different subgroups for possible differences.

Because of the MMPI "code type" tradition, it is not uncommon to analyze relationships by presenting MMPI correlates in the form of relevant base rates or means associated with each of several distinct code types. (The actuarial atlases of Marks, Seeman, & Haller, 1974, and Gilberstadt & Duker, 1965, are well-known examples.) One distinct potential advantage of this approach is that certain "configural" relations, reflecting interactions among MMPI scales in relation to criterion variables, will be used. For example, if correlates of Scale 7 differ depending on the subject's scores on additional scales, say 2, 4, or 8, then the use of different code types such as 2-7, 4-7, 2-7-8, and so on, permits one to capitalize on these interactions.

But reliance on code types has disadvantages. One is that some information is inevitably lost when a profile is assigned to a code type. Another disadvantage is the small

number of classifiable subjects for many code types, even in rather extensive studies. These classification problems are often unnecessary, since many important relations between MMPI and external criteria are often not configural but essentially linear. That is, important relations may be adequately described by the linear relations existing in the *total* sample between one or more MMPI variables and other measures. One example is Goldberg's (1965) analysis of methods of distinguishing psychotic from neurotic patients on the basis of the MMPI. Goldberg showed that a simple linear combination of several clinical scales did just as well as the highly configural Meehl-Dahlstrom rules. Although the Goldberg analysis is one of the few well-documented examples, we have little doubt that (e.g., in the material from which Marks et al. 1974, and Gilberstadt & Duker, 1965, atlases have been derived) a number of linear relations between single or several MMPI scales and important nontest data are hidden, other than the psychotic versus neurotic distinction. One example is an apparent straightforward (linear) relationship between scores on Scale 4 and alcoholism in the Gilberstadt and Duker (1965) sample (pointed out by them). This example illustrates another disadvantage of exclusively relying on the "code-type approach": The method may *exploit* but does not *reveal the nature of* the relations, linear or nonlinear, that may exist in one's data.

Goldberg's monograph is one example of how such relations can be pursued systematically, albeit in this case with negative results with respect to nonlinear relations. However, we believe that even nonlinear relations may emerge from systematic analyses provided the search is guided by a certain degree of theorizing permitting a focus on a smaller set of possible configurations, thus reducing the probability of drowning a few actual configural relations in a sea of unreplicable chance relationships. The reason is that without some theoretical constraints, the number of configural patterns that would have to be considered in an exhaustive search easily becomes extremely and unmanageably large, thus requiring unattainably large sample sizes to minimize the occurrences of chance patterns.

We find, then, that code and profile types provide convenient ways of assimilating the information contained in a set of MMPI scores. But in spite of the continuing advocacy (and plausibility) of typological classifications, acceptance of such classifications should be provisional rather than uncritical. We still do not know a great deal about how much and when type of membership would add to the information already contained in a (more parsimonious and psychometrically conservative) dimensional predictor, for example, an appropriate linear regression formula. Research on this question seems quite feasible and could give interesting results.

Assessing Profile Change

The measurement of change is methodologically complex, and the researcher engaged in such measurement should become aware of the difficulties involved (Cronbach & Furby, 1970; Fiske & Rice, 1955; Mauger, 1972; see especially Dahlstrom et al., 1972, chap. 7). We cannot review all of the relevant issues in the limited space of this article. However, it is important to keep in mind that a simple difference in MMPI mean scale scores on retest may not indicate that the individuals involved have necessarily changed as a result of some interposed treatment. Familiarity with and critical understanding of such concepts as "residual gain" are essential (e.g., Cronbach & Furby, 1970). To balance somewhat the note of pessimism in Cronbach and Furby's article, it should be pointed out that experimental designs containing comparison groups can be effective tools for understanding change. One substantive issue that the investigator should keep in mind is that MMPI measures appear to tap a mixture of changeable and stable characteristics. Some of the scales (e.g., *D*) appear to be reflective of "state" as well as "trait" characteristics and are sensitive to mood changes. Other scales focus on "biographical" factors (*Si* or *Pd*) and seem relatively more stable. What is the meaning of a particular MMPI scale change? If not a statistical artifact, does it reflect a change in affective state, a permanent change, a change in self-presentation?

In addition, a change on a particular scale

is not necessarily best described in terms of the name of the scale in question. For example, a significant change on the *Pd* scale may be due primarily to changes on a subset of *Pd* items reflecting a negative mood state; content-homogeneous MMPI scales are certainly less potentially misleading in the interpretation of change than the more heterogeneous clinical scales. These problems should be addressed in any thoughtful discussion of MMPI data pertaining to change. As a general point, it is good to keep in mind that some scales may be useful for *reflecting* change, say, resulting from intervention, but other scales may be more useful for *predicting* response to treatment (without necessarily reflecting the effects of treatment).

On the whole it may be true that the original method of developing the MMPI favored the selection and construction of relatively stable items and scales, respectively. None of the original work was directly focused on measuring change. Subsequent efforts at using MMPI items to detect changeability or to develop scales that would give clues to potential for change have not met with much success (Mauger, 1972; Pepper, 1964). The "stability" of the MMPI is shown by the fairly consistent finding that about 87% of the MMPI items are answered in the same direction on retest (Butcher & Gur, 1974; Goldberg & Jones, 1969; Schofield, 1948; Ullmann & Wiggins, 1962). Consequently, the number of items that can be expected to vary on retest is relatively small.

Reporting Group Data

What do we know from a group mean profile that summarizes a set of MMPI scores? Can we assume that if the group average is a 278" profile type that the established personality correlates for the 278" profile necessarily fit the group as a whole or some subset of individuals in the group? No, sometimes we fall into the trap of drawing such a conclusion. It may actually be the case that *no* individual in the group has the code type corresponding to the group mean score. Researchers who are not content to present merely the means and standard deviations of individual scales could report the percentages

of the different code or profile types occurring in their sample.

In summary, the MMPI continues to be a widely used research instrument as well as a clinical assessment inventory. Reasons for its wide application include its easy administration, its objective scoring, the volume of data demonstrating its validity, and the automation of its interpretation. The MMPI is such an easily used research instrument that it is sometimes misapplied or the data obtained with it are incorrectly analyzed by researchers who are not familiar with some of its limitations or peculiarities. The MMPI can play and has played a useful role in significant research. The main prerequisites are the investigator's long-term and genuine concern with an important problem and her/his ability to draw on the store of substantial methodological knowledge and wisdom, accumulated in the field of personality assessment in general (e.g., Wiggins, 1973) and in the area of MMPI research in particular (e.g., Dahlstrom et al., 1972, 1975).

Methodological and Interpretive Problems of Single-Case Experimental Designs

Alan E. Kazdin
Pennsylvania State University

Single-case experimental designs have been used with increasing frequency in clinical research. These designs are uniquely suited to evaluating treatment effects with individual clients. Although treatment is evaluated by comparing baseline and treatment phases, the manner in which this is accomplished varies as a function of the specific design. Typically, the comparison is replicated over time (ABAB design) or across different behaviors (multiple-baseline design). Several methodological problems frequently arise in single-case designs, such as deciding when to alter phases or conditions in the experiment, ensuring that the intervention is implemented, comparing alternative treatments unconfounded by sequence effects, and ensuring that data are collected reliably. Many interpretive problems of single-case designs stem from the criteria used to evaluate treatment. Whether treatment produced a reliable effect usually is determined by visual inspection of the data. In addition, single-case research has been concerned with the clinical importance of treatment effects. The ambiguity of these criteria, relative to statistical tests used in group designs, presents unique problems for evaluating treatment. The present article considers methodological and interpretive problems that frequently arise in single-case experiments.

Single-case experimental designs are used increasingly in clinical research. Although these designs can evaluate interventions with groups of subjects, their unique contribution is that they can experimentally evaluate interventions for the individual client. Hence, the designs offer a distinct methodological advance over the traditional uncontrolled case study, which provides only suggestive information about the effects of treatment on a client's behavior.

Several characteristics and problems of single-case experimental designs are still un-

familiar to many investigators who might profit from their use. The designs and their execution are not inherently complex. However, they do differ in important ways from traditional group research with which most investigators are familiar. The present article describes several methodological problems that frequently arise in single-case experiments. These encompass planning the research, making decisions during the investigation, and evaluating the results. To understand these methodological problems, the basic rationale of single-case experiments and the manner in which intervention effects are demonstrated need to be discussed briefly.

This manuscript was completed while the author was a Fellow at the Center for Advanced Study in the Behavioral Sciences, Stanford, California. Fellowship support was obtained from the Foundations Fund for Research in Psychiatry, National Institute of Mental Health Grant 1-T32-MH14581, and the Spencer Foundation, which the author gratefully acknowledges.

Overview of Single-Case Experimental Designs

Basic Rationale

The rationale of single-case designs is similar to traditional group research. In traditional experimentation, the effect of an intervention is assessed by comparing performance

under the influence of different levels of a given variable. Typically, different groups of subjects or the same group are exposed to different experimental conditions. The essential feature of traditional research, as well as single-case research, is a comparison of performance under different conditions. The manner in which the comparison is made in single-case experiments departs from traditional designs.

Single-case experimental designs usually begin by observing a client's behavior before treatment for a period of at least several days. This period, referred to as a baseline phase, serves a twofold purpose. First, the data collected during baseline describe the existing level of performance and hence provide information about the extent of the client's problem. Second, the data serve as a basis for predicting the level of performance for the immediate future if treatment is not provided. Even though the descriptive function of baseline data is important for characterizing the extent of the problem, from the standpoint of design, the predictive function is central.

To evaluate treatment, it is important to have a clear idea of what behavior would be like in the immediate future with no intervention. A projection of baseline performance into the future is the implicit criterion against which treatment is evaluated. Thus, a stable level of performance during baseline is important before beginning treatment. A stable rate of performance is characterized by the absence of trend (slope) in the data and only slight or moderate variability in performance. Once a stable rate is obtained, treatment can be implemented. Assessment of behavior is continued while treatment is in effect to determine whether performance departs from baseline levels. If treatment is effective, the actual level of behavior should deviate from the projected level of behavior from baseline performance. Data during the treatment phase serve another function. These data also provide a new level of performance and can be used to predict how the client will behave in the immediate future if treatment is continued. After performance stabilizes, the treatment can be withdrawn to reassess whether performance under these conditions deviates

from the predicted level. Also, by withdrawing treatment, the investigator tests directly whether the original baseline level of performance would have continued at a given level.

Essentially, data in separate phases of single-case designs provide information about present performance, predict the probable level of future performance, and test the extent to which predictions of performance from previous phases were accurate. By repeatedly altering experimental conditions in the design, there are several different opportunities to compare phases and to test whether performance is altered by the intervention. If performance changes in response to alterations of the experimental conditions, the change can be more parsimoniously accounted for by the experimental conditions than by extraneous events.

Illustrative Designs

The manner in which treatment effects are demonstrated varies as a function of different designs. There are several designs, each of which includes many variations (see Baer, Wolf, & Risley, 1968; Hartmann & Hall, 1976; Hersen & Barlow, 1976; Kazdin, 1978b; Leitenberg, 1973; Ulman & Sulzer-Azaroff, 1975). Two designs warrant brief mention because they are the most commonly used in single-case experimentation and because they serve as a useful point of departure for describing methodological problems for single-case experiments. These designs are the ABAB, or reversal, design and the multiple-baseline design.

The ABAB design evaluates an intervention by alternating the baseline condition (A phase) when no treatment is in effect with the intervention (B phase). Baseline data are collected until the client's performance stabilizes. At this point, the intervention is implemented. When performance again stabilizes or shows a trend that clearly departs from the projected performance of baseline, the intervention usually is withdrawn (second A phase). Finally, as performance shifts to a new level, the intervention is reinstated (second B phase). Typically, behavior again changes in response to the intervention. Systematic changes in behavior associated with

variation of the experimental conditions, particularly when replicated at different points in the design, strongly suggest that the intervention accounts for the results.

The multiple-baseline design, used less frequently than the ABAB design, demonstrates the effect of the intervention without withdrawing treatment. In this design, the effect of the intervention is demonstrated by showing that behavior change accompanies introduction of the intervention at different points in time. Although there are different versions of the design, a commonly used version is the multiple-baseline design across behaviors. In this version, baseline data are gathered across two or more different responses of a single subject (or group of subjects). After each behavior shows a stable rate, the intervention is applied to only one of the behaviors. Baseline conditions remain in effect for the other behavior(s). Typically, the behavior to which the intervention was applied changes, whereas the other behaviors remain at baseline levels. When all responses show a stable rate, the intervention also is applied to the second behavior; remaining behaviors continue under baseline conditions. This procedure is continued so that the intervention is introduced to one response at a time. A causal relation between the intervention and behavior is demonstrated if each response changes when and only when the intervention is introduced. If a change in behavior at the point that the intervention is introduced is replicated across several behaviors, this provides a convincing demonstration that the intervention was responsible for behavior change.

There are other designs that demonstrate intervention effects in ways that vary in detail from the ABAB and multiple-baseline designs described briefly above. In each of these designs, the fundamental comparison to evaluate treatment is the performance of baseline and intervention phases. The comparison usually is based on replications within a single subject so that repeated opportunities are available to assess whether the intervention accounted for change. It is important to understand the basic rationale for evaluating treatment that transcends the diverse designs, because ambiguities in results of single-case

experiments frequently derive from not meeting the conditions required by the designs.

Common Methodological Problems

Several methodological problems are common in investigations using single-case experimental designs. Many problems are independent of the specific designs that are used. Hence, it is not important to fully detail the specific designs available in single-case experimentation as long as the rationale is illustrated with samples of the most frequently used designs. Areas in which problems frequently arise are altering phases in the designs, checking whether the intervention was manipulated correctly, comparing alternative interventions, and gathering reliable data on client behavior.

Altering Phases or Conditions During the Experiment

Traditionally, research designs are preplanned so that most of the details are arranged before subjects are studied. In single-case experimental designs, a number of important decisions can be made only as the data are collected. Decisions such as how long baseline data should be collected and when to present or withdraw experimental conditions are made during the investigation itself. The experimenter needs to decide when to alter phases in the design in such a way as to maximize the clarity with which inferences can be drawn about the intervention. Each of the single-case designs usually begins with a baseline phase. Treatment is evaluated ultimately by comparing performance across baseline and intervention phases, as described earlier. For these comparisons to be made easily, one has to be sure that the changes from one phase to another are likely to be due to the intervention rather than to a continuation of an existing trend. A fundamental design issue is when to change phases to maximize the clarity of data interpretation.

There are no clear rules for altering phases. Understandably, investigators differ when conditions are altered. Yet, the point at which conditions are changed is a very important issue, because subsequent evaluation of inter-

vention effects depends completely on how clear the behavior changes are across phases. The usual rule of thumb is to alter phases in which the data are stable. Stability refers to the absence of trend and relatively small variability in a given level of performance. Trends and extensive variability during any of the phases, particularly baseline, can interfere with evaluating treatment.

Trends in the data. Ideally, baseline data should show no trend or slope prior to implementing the intervention. One of two different trends may be apparent. First, behavior may be changing in the direction opposite from that which is to be achieved during the intervention. For example, a psychotic patient may show a reduction in rational statements during baseline. Because the intervention will attempt to alter behavior in the opposite direction (increase rational statements), this initial trend in baseline is not likely to interfere with subsequent conclusions about the intervention. As a general rule, when the intervention is designed to change behavior in a direction opposite from the trend in baseline, the trend is not problematic. The rule can be extended to all changes in conditions so that trends, opposite from what the anticipated data will show in the next phase, should not interfere with drawing inferences about treatment.

In contrast, the baseline trend may be in the same direction that the intervention is likely to produce. Essentially, baseline may show improvements in behavior, and one might question the need to intervene at all. However, even if improvements are made, as might be the case with an autistic child's severe self-injurious behavior during a baseline period when attention for such behavior is inadvertently withheld, the changes may be so slow that some intervention is needed. For example, a child engaging in frequent head banging might gradually decrease the response, but the reduction could be so gradual that serious self-injury might be inflicted unless the behavior is quickly eliminated. Despite the desirability of intervening in many situations in which baseline trends move in the direction of therapeutic change, evaluating the effect of the intervention in these situations is extremely difficult. The in-

tervention has to produce very marked change to draw unambiguous conclusions. Because of this difficulty in evaluating interventions with systematic trends in the direction of therapeutic change in baseline, the usual recommendation is to wait for baseline to stabilize so that there is no trend before intervening (Baer et al., 1968). This cannot be done in many clinical situations in which treatment is needed quickly.

When baseline shows a trend toward improvement, two major alternative strategies are available. First, an ABAB design can be used in which a procedure for changing behavior in the opposite direction can be alternated with the intervention. For example, baseline can consist of reinforcing *decreases* in the desirable behavior, whereas interventions can reinforce *increases* in the same behavior. This alternative can dramatically demonstrate that treatment accounted for change (e.g., Ayllon & Haughton, 1964). The design is experimentally sound but clinically untenable because it includes specific provisions for making the client's behavior worse.

A second solution is to select designs in which trends in the data are unlikely to affect each of the baselines observed (multiple-baseline design) or in which trends are not relevant to evaluate different treatments (simultaneous treatment design). A third solution is to use statistical techniques that can evaluate the effect of the intervention relative to the baseline trend. Specific statistical techniques such as time-series analysis can take into account baseline trends and assess whether the intervention has made a reliable change over and above what would be expected from continuation of the trend (see Glass, Willson, & Gottman, 1974; Jones, Vaught, & Weinrott, 1977; Kazdin, 1976).

Intrasubject variability. In addition to trends, excessive variability in the data can interfere with drawing conclusions about treatment. As a general rule, the greater the variability in the data, the greater the difficulty in demonstrating behavior change. Excessive variability is a relative matter that depends on the initial level of behavior during baseline, the magnitude of change achieved during the intervention, the degree of change desired, and other factors. In the

extreme case, baseline performance of the target behavior may vary daily from 0 to 100%, that is, to each extreme of an assessment continuum. Such baseline data probably cannot be used to predict a specific level of future performance and hence would not provide an adequate base against which the data during an intervention phase could be compared.

To facilitate treatment evaluation, investigators sometimes reduce the *appearance* of variability in graphical presentation of the data by averaging data points across consecutive days or sessions. The procedure consists merely of combining days of data and averaging across the number of combined data points. By representing 2 or more days with a single averaged data point, fluctuations are reduced substantially and the data appear more stable. Although such a procedure distorts the day-to-day pattern of performance, the data in different phases can be readily compared.

Whenever possible, it is better to identify and control sources producing variability than merely to average the data. The variability may result from sources that are important to identify before implementing treatment. For example, unreliability in scoring behavior may contribute to excessive variability. The client may perform the target response relatively consistently. Yet observers may change criteria in scoring the behavior, which may add considerably to the variability. Such variability should be controlled by ensuring that observations are scored consistently across observers and over time. Other sources may account for variability, such as changes in cues in the environment. For example, the presence of one individual rather than another (e.g., mother rather than father) may control the rate of behavior. If variability is excessive, an attempt can be made to assess the stimulus conditions that mediate differences in response rates. Identification of some of the factors that contribute to variability also may provide cues about the factors controlling behavior and provide practical suggestions for treatment.

For whatever reason, behavior may simply be quite variable. Indeed, the goal of the program may be to alter the variability of the

client's performance rather than the mean rate. Usually, large data fluctuations, especially during baseline, make evaluation of the intervention difficult. Such fluctuations are a signal to the investigator to either look for the controlling variables or to redefine the behavior or conditions of assessment to reduce variability. Continuation of the program in the face of excessive variability eliminates the possibility of drawing inferences about treatment.

Duration of the phases. How long phases will be in a single-case experimental design usually is not specified in advance of the investigation. The reason for this is that the investigator needs to examine the data and to determine whether the information is sufficiently clear to make predictions about performance. The presence of trends or excessive variability indicates that the information may not be sufficiently clear. Hence, it is useful to wait for a more stable rate of performance to emerge. A common methodological problem is altering phases before a clear pattern emerges. For example, most of the data may indicate a clear pattern for baseline. Yet, after a few days of relatively stable baseline performance, one or two data points may be higher or lower than the previous data. The question that immediately arises is whether a trend is emerging in baseline or whether the data points are merely a part of the normal variability. It is wise to continue the condition without shifting phases just to be sure. If 1 or 2 more days of data reveal that there is no trend, the intervention can be implemented as planned. The increase of data provides an increase in confidence that there was no emerging trend and facilitates subsequent evaluation of intervention effects.

Occasionally, an investigator may obtain an extreme data point during baseline in the opposite direction of the change anticipated with treatment. This extreme point may be interpreted as suggesting that if there is any trend, it is in the opposite direction of treatment effects. Thus, investigators often shift phases when an extreme data point is noted in the previous phase in the direction opposite from predicted effects of the next phase. Yet, extreme scores in one direction are likely to be followed by scores that revert in the di-

rection of the mean. Thus, if the observation indicates a particularly high score on one occasion, the next occasion is likely to show a less extreme score. This characteristic is known as *statistical regression* and is a function of the correlation between consecutive data points.¹

It is important to be aware of the possibility of regression. Because the extreme score in one direction is likely to be followed by a much less extreme score that reverts toward the mean, it is unwise to shift phases following highly extreme scores. Shifting phases at this point would capitalize on regression. This improvement in performance would appear to be a function of shifting from baseline to intervention phases. However, the improvement might be a function of regression. As data continue to be collected in the new phase, the investigator could, of course, see whether the intervention is having an effect on behavior. However, if mean levels of performance are compared across phases, shifting phases at points of extreme scores could systematically bias the average performance in each of the phases. This could influence the conclusions that are drawn, especially if the phases are relatively brief.

Currently, there are no agreed upon objective decision rules for alternating phases in single-case experimental designs. Occasionally, investigators have attempted to specify objective criteria in advance that indicate the conditions under which baseline and experimental conditions will be alternated (e.g., Scott et al., 1973; Wincze, Leitenberg, & Agras, 1972). For example, phases can be shifted when variability about the mean level of performance falls within a specific range for a period of 5 days or when a given number of consecutive data points are not in the same direction above (or below) the mean. Attempts to develop an objective preset rule for an important design decision that has remained primarily subjective are laudible. However, the rules have not been sufficiently developed to this point to routinely exclude emerging trends or the influence of regression due to extreme scores in the data.

Checking the Intervention

In single-case experiments, the investigator manipulates specific conditions and assesses

their effects on behavior. If the dependent measure reflects change and the replication requirements within the design are met, the investigator is likely to assume that the intervention was responsible for behavior change. In most behavior modification interventions, in which single-case experimental designs are used with the greatest frequency, the intervention consists of the behavior of individuals (e.g., parents, teachers, peers) who interact with the client (e.g., child). For example, parental attention can be used to alter the behaviors of conduct problem children at home. When the intervention consists of behaviors in natural situations, the investigator has no assurance that the intervention is carried out correctly, or indeed is even implemented at all. This situation is to be contrasted with laboratory experiments in which the intervention can be implemented by reading instructions or playing an audio or video tape recorder and in which standardization of the intervention can be more readily assured.

When the behavior of individuals in contact with the client is the independent variable, it is especially important to gather data to ensure that the intervention is carried out. This is essential for at least three reasons. First, the behaviors of individuals who interact with the clients in naturalistic settings often are difficult to change (e.g., Breyer & Allen, 1975). Thus, an investigator cannot automatically assume that behavior-change agents will engage in the desired behaviors after receiving instructions or reminders. Second, when changes are made in behavior-change agents, they often are short-lived (e.g., Kazdin & Moyer, 1976). There is no assurance that once the intervention is implemented it will continue to be carried out in the appropriate fashion. Finally, individuals responsible for altering client behavior may show changes in their behaviors that extend

¹ The lower the correlation between consecutive data points, the greater the regression toward the mean. The reason for this is that the lower correlation between consecutive data points, the greater the amount of error in the scores. The random error that is likely to be present in an extreme score on one occasion is not likely to be present on the next occasion. Thus, a score that departs considerably from the overall mean is likely to be followed by a much less extreme score.

beyond the confines of the intervention (Chadwick & Day, 1971; Trudel, Boisvert, Maruca, & Leroux, 1974).

Even if experimental results meet the design requirements and are replicated across phases, precision can be increased by supplementary data showing that the intervention was carried out in the desired fashion. Without these data, the systematic changes in client behavior may be the result of some other influence in the setting. Indeed, it is quite possible given existing evidence on the performance of behavior-change agents that some aspect of their behavior other than the intended intervention led to change (Kazdin, 1977d).

Often it is desirable to have information about variables that may covary with the intervention and could plausibly account for change. For example, verbal approval and disapproval have proven to be very potent variables in altering child behavior. In programs evaluating other interventions (e.g., token reinforcement, nonverbal approval), it is essential to collect data on verbal behaviors of the behavior-change agents as well to assess whether they have covaried with the intervention (e.g., Kaufman & O'Leary, 1972; Kazdin & Klock, 1973). This assessment is important in situations in which behavior change might result from events that already have been shown to influence behavior in previous research and may be more plausible as influences than the variable of direct interest.

Comparing Alternative Interventions

Investigators using single-case designs frequently are interested in assessing the relative efficacy of different treatments with a given client. Comparing different treatments within a single set of subjects or a single subject is difficult because of the likely confound of treatments with sequence or order effects. It is still common to see investigators compare two or more different interventions in a version of an ABAB design. As a simple case, the design may be represented as an ABCA design (where A refers to baseline and B and C refer to alternative treatments). If performance levels of the client differ under the different treatments, the investigator can make statements about the relative efficacy of the

treatments. However, two treatments invariably are confounded with the order of appearance. One cannot interpret whether the first (or second) intervention led to more (or less) behavior change because of the treatment itself or because of the sequence in which it appeared.

A common technique is to add a return-to-baseline condition (an A phase) between the two interventions to show that original baseline level of performance is recovered (an ABACA design). Even if baseline levels are the same prior to each (B,C) intervention, this still does not correct for the confound of sequence effects. Merely because baseline phases prior to each intervention were equal in the level of performance does not mean that they are comparable in all other respects. Behavior change is not equally difficult to achieve on repeated occasions in which a treatment is presented and withdrawn. Additional interventions may need to be more or less effective than prior ones to effect change.

Investigators often conduct a more complex version of the design in which the effects of treatment are replicated at different points in the design for the subject. For example, in an ABCABC design, each treatment (B,C) is given twice. Even here, any conclusions reached about treatments are restricted to the particular order of treatment. The efficacy of C may result from the fact that it has followed B. The effects of C when presented without this prior history may be completely different. In short, the fixed sequence of treatments may lead to multiple-treatment interference (see Campbell & Stanley, 1963). Conclusions about the treatments must be tempered by acknowledging the possible contribution of one treatment on later treatments.²

The main problem with sequence effects in single-case experimental designs stems from the fact that investigators frequently rely on versions of the ABAB design. If this design

² Although the discussion of sequence effects may seem of academic interest, this is not the case. Both laboratory animal investigations (Grice & Hunter, 1964) and applications with clinical problems (White, Nielson, & Johnson, 1972) have shown that the effects of a given intervention may be affected by the treatments presented immediately before.

were used to compare treatments, more than one subject would be needed to ensure that the treatments are counterbalanced. Only if the treatments are presented in a different sequence can the investigator be assured that the interventions are differentially effective independent of the order in which they appear. Actually, using more than one subject is not a very useful solution. Unlike group designs in which the different sequences are replicated across several subjects, a single-case design with only two subjects would not allow separation of the sequence effects from unique subject characteristics. That is, if two treatments produce different effects across two subjects, the investigator cannot determine whether the order was important or whether the subjects merely responded differently to the treatments.

If the investigator is interested in single-case designs for comparing treatments, the ABAB design and its variations probably should be avoided. There are alternative single-case experimental designs suited to comparisons of different treatments. These include the multiple-element baseline or multiple-schedule design (Leitenberg, 1973; Ullman and Sulzer-Azaroff, 1975) or the simultaneous-treatment design (Kazdin, 1977c). In these designs, the separate interventions can be presented to an individual subject in such a way that the interventions are not confounded by sequence effects. Specifically, separate interventions are presented concurrently but can be balanced across conditions of administration.

Interobserver Agreement

In most single-case experimental designs, overt client behavior is assessed daily over the course of baseline and intervention conditions. In the majority of cases, observers record whether behavior has occurred based on their judgment and the definition of the response as originally specified. Occasionally, automated recording devices (e.g., time clock, plethysmograph), equipment requiring little or no judgment (e.g., scale), or devices that make scoring merely a clerical task (e.g., key to a paper-and-pencil test) are used, and there is little question whether observations are con-

sistent and accurate. In other cases, in which human judgment may figure more prominently in scoring the response, doubt can be raised about the adequacy of the assessment procedure and the consistency with which observations are made. In these latter cases, it is essential to assess the extent to which observers are collecting data consistently and accurately. Actually, assessment of client behavior and interobserver agreement might be viewed as purely measurement problems and be distinguished from design issues. However, single-case designs rely on behavioral observations, and assessment issues directly relate to evaluation of intervention effects.³

Interobserver agreement assesses whether the client's behavior is observed consistently. With low agreement, the data may differ greatly depending on who is scoring the behavior. Variation in the data due to the observer adds to any variability in client behavior and obscures actual performance. As noted earlier, evaluation of the intervention depends on obtaining data that have relatively little variability. Measurement error contributes to variability and makes subsequent evaluation more difficult. Indeed, if variability due to assessment error is extremely large, establishing a stable rate of behavior and evaluating the intervention may be impossible.

Evidence suggests that observers may stray from original behavioral codes in scoring client behavior (Kent & Foster, 1977). To ensure sustained accuracy and consistency in observer assessment, it is useful to check each observer against an independent standard and calculate the amount of agreement. Aside from a general trend to deviate from the original behavioral codes, observers may develop idiosyncratic coding tendencies so that they may

³ The assessment of interobserver agreement in single-case experiments has been a topic of major discussion in recent years. Basic issues are still actively discussed, including the manner in which interobserver agreement should be assessed, the conditions under which such methods are appropriate, the sources of bias that obscure interpretation of agreement data, and similar factors. These issues have been described in several publications (e.g., Hawkins & Dotson, 1975; Kent & Foster, 1977) including an invited series of articles in the *Journal of Applied Behavior Analysis* (1977, 10[4]).

see behaviors different from other observers. Periodic checks on interobserver agreement may help evaluate whether changes in scoring are occurring and whether particular observers are responsible for any of these changes.

Actually, research on interobserver agreement has revealed several factors that need to be taken into account when obtaining checks on observers (see Kazdin, 1977a; Kent & Foster, 1977). Observer awareness that agreement is being checked, who the other observer is, and reactions of the experimenter to the data that are reported have influenced interobserver agreement and the nature of the data obtained. As a general rule, a minimal condition for observation of overt behavior is the assessment of interobserver agreement at different points throughout the experiment. Agreement checks need to be dispersed over each of the phases to ensure that observer biases and changes in criteria for scoring responses are not likely to be confounded with treatment. Ideally, interobserver agreement should be assessed unobtrusively, because observer awareness that agreement is being checked influences the data. However, experimental arrangements required to accomplish unobtrusive agreement checks are difficult to meet (Kazdin, 1977a).

Issues in Data Interpretation

A major issue in evaluating treatment effects in research is the internal validity of experimental findings (Campbell & Stanley, 1963). Internal validity refers to assessing whether the intervention accounted for the results and essentially pertains to experimental design considerations that rule out potential sources of confound. The issue of internal validity is central to all research. However, single-case designs differ from traditional research in the criteria for determining whether an intervention accounted for the results. Failure to understand the criteria for evaluating results constitutes a major methodological issue.

Criteria for Evaluating Change

Single-case experimental designs attempt to structure the situation so that the effects of

the intervention and extraneous variables can be distinguished. The replication of intervention effects over time or across baselines is designed to make implausible the influence of various threats to internal validity. Just as the designs depart from traditional group experimentation, so do the criteria for evaluating the effectiveness of an intervention on behavior. Two criteria have been used to evaluate treatment effects in single-case experiments, namely, the experimental criterion and the therapeutic criterion (Kazdin, 1978b; Risley, 1970).

Experimental criterion. The experimental criterion refers to a comparison of behavior during the intervention with what it would be like if the intervention had not been implemented. This criterion, of course, characterizes group research designs as well. However, single-case experiments usually do not fulfill this criterion by appealing to statistical analyses. Rather, the experimental criterion is met by replicating treatment effects over time. Repeatedly showing that alteration of contingency changes the level of performance in relation to the previous phase fulfills the experimental criterion. The strength of the demonstration derives from showing that performance during a given phase violates the predicted level of performance of the prior phase before the intervention was introduced. Each design accomplishes the replication of treatment effects in a different way. For example, in the ABAB design, the intervention is replicated over time for a single subject or group of subjects. Similarly, in a multiple-baseline design, the effect is replicated across separate baselines.

In practice, whether the results meet the experimental criterion is determined in various ways. First, if performance during an intervention phase does not overlap with performance during the baseline phase when these data points are plotted over time, the effects usually are regarded as reliable. The replication of nonoverlapping distributions during different treatment phases strongly argues for the effects of treatment. Second, a more typical criterion for experimental evaluation is related to the trends in each phase. If baseline and intervention conditions show changes in trends as the phases are alternated, the re-

liability of the data and effects of the intervention usually are inferred.

One of the problems with experimental evaluation of single-case method designs is that they have relied almost exclusively on visual inspection to determine whether the magnitude of change across phases is significant. The problem with visual inspection is that individuals who peruse the data may not see eye to eye. For example, Jones, Weinrott, and Vaught (Note 1) demonstrated considerable disagreement among judges asked to visually inspect the data from the same single-case experimental design.

Recently, statistical evaluation of single-case data has received increased attention (Kazdin, 1976; Michael, 1974). Such evaluations are likely to be useful in situations in which the ideal conditions such as stable baselines and relatively small variability cannot be met. Thus, the reliability of treatment effects can be examined in situations in which visual inspection might be weak or unreliable. However, the use of statistics with single-case designs is controversial (Michael, 1974). Also, statistical tests appropriate for single-case analyses are less familiar to most investigators because they are not the ones commonly taught in graduate statistics in psychology. Further, the tests include relatively restrictive assumptions that may dictate selection of the design and the manner in which treatment is implemented (see Kazdin, 1976). Because of the infrequent use of statistics in single-case experiments and lack of familiarity with the statistical properties of the tests, it is no surprise that inappropriate applications of statistical tests already have entered the literature. In any case, statistical tests are available for evaluating the reliability of intervention effects in single-case experimental designs. These tests have been illustrated at length elsewhere (Jones et al., 1977; Kazdin, 1976).

Therapeutic criterion. The therapeutic criterion for evaluating single-case experimental designs refers to the value or importance of behavior change, that is, the clinical significance of treatment effects. This criterion refers to whether the extent of behavior change achieved during treatment enhances the client's functioning in everyday situations

(Risley, 1970). Implicit in this criterion, of course, is that the behavior selected for alteration is itself of clinical or social importance.

The therapeutic criterion is more difficult to satisfy than is the experimental criterion. Showing a reliable treatment effect, through visual inspection or statistical analysis, has no necessary bearing on the importance of the change. For example, a single-case demonstration might well show a reduction of self-destructive behavior from 100 to 50 instances per hour. Even though the reduction is relatively large and might meet the most stringent statistical test, the remaining level of behavior is far removed from the "normal social interaction" to which the individual might someday return. To be of unequivocal therapeutic significance, the intervention would need to eliminate self-destructive behavior.

The ease of evaluating the importance of clinical change in the above example derives from the fact that intense destructive behavior is maladaptive whenever it occurs. Yet, for many behaviors, the level and intensity of behavior rather than merely its presence or absence dictate whether it is acceptable. This makes satisfying the therapeutic criterion much more difficult. Indeed, the precise criterion for evaluating whether the effects of treatment are clinically important is difficult to specify. Part of the reason is that individuals in everyday life (e.g., parents, teachers, friends) and the individual himself or herself determine the level of behavior that is acceptable or deviant.

Recently, single-case experimental methodology has made efforts to assess objectively whether the effects of treatment are clinically significant. The procedures for assessing the clinical importance of treatment effects are referred to as *social validation* (Wolf, Note 2) and have been incorporated into an increasing number of investigations (Kazdin, 1977b). Generally, social validation of treatment effects consists of determining whether behavior changes are clinically important in the social context in which the client functions. This is accomplished in one of two ways, referred to as social comparison and subjective evaluation methods (Kazdin,

1977b). With the *social comparison method*, the behavior of the client before and after treatment is compared with the behavior of "nondeviant" peers. The question asked by this comparison is whether the client's behavior after treatment is distinguishable from the normative range of behavior of his or her peers. With the *subjective evaluation method*, behavior is evaluated by individuals who are likely to have contact with the client to determine whether the change made during treatment is important. The question addressed by this method is whether behavior changes demonstrated in treatment lead to qualitative differences in how the client is viewed by others.

In using the social comparison method to evaluate treatment, it is essential to identify individuals who are similar to the client in subject and demographic variables but who have been identified as showing acceptable behavior. Presumably, peers of the client identified in such a fashion should differ markedly from the client in the target behavior prior to treatment. After treatment, the behavior of the client and peers can be compared again. If treatment has effected clinically significant change, this should be demonstrated by showing that the client's behavior has moved to within acceptable, that is, "normative," levels of functioning. Several studies have shown that treatment effects bring initially deviant levels of behavior within normative levels for social interaction or conduct problems of children (e.g., O'Connor, 1972), basic reading skills of the mentally retarded (Azrin & Armstrong, 1973), locus of control and self-concepts of delinquents (Eitzen, 1975), social skills of unassertive college students (e.g., McFall & Twentyman, 1973), and others (see Kazdin, 1977b, for a review).

In applying the subjective evaluation method, individuals who normally interact with the client or who are in a special position (e.g., through expertise) to judge a particular behavior provide global evaluations to assess how well the client is functioning. Essentially, the global appraisal is used to evaluate whether the specific behaviors changed have implications for how the client is viewed by others. Obviously, the global ratings are used only to supplement objective behavioral

data, since studies have demonstrated that global judgments are much more likely to reflect bias than are specific objective measures (Kazdin, 1973; Kent, O'Leary, Diamant, & Dietz, 1974; Schnelle, 1974).

The subjective evaluation method can be used both to help identify important behaviors to assess and focus on in treatment as well as to evaluate qualitative improvements associated with behavior change. Studies have used global assessments prior to treatment to determine whether the specific behaviors that are observed and included in treatment are relevant to individuals in contact with the client in everyday situations (e.g., Werner et al., 1975). More commonly, subjective evaluations are used to evaluate pretreatment and posttreatment levels of behavior. Several studies have shown that behavior changes have improved qualitative global judgments of individuals in contact with the clients for programs training delinquent girls how to communicate appropriately with others (e.g., Maloney et al., 1976), developing public-speaking skills in adults (Fawcett & Miller, 1975), training problem-solving skills of lower socioeconomic adults in positions that may influence decision making (Briscoe, Hoffman, & Bailey, 1975), and altering performance of conduct problem children (Kent & O'Leary, 1976).

Social comparison and subjective evaluation methods are not without problems. For example, identifying appropriate peer groups to which client behavior can be compared, deciding whether normative levels are the appropriate standard or themselves should be subject to change, and determining precisely what global judgments actually mean are only some of the problems for evaluating the therapeutic criterion (Kazdin, 1977b). However imperfect, the methods show considerable promise in assessing the clinical importance of behavior change and need to be incorporated routinely into clinical research. Although the bulk of studies using social validation procedures relied on single-case experimental designs, many of the studies were traditional between-group designs (e.g., Kent & O'Leary, 1976; McFall & Twentyman, 1973). The validation procedures are not restricted to any particular design and are emphasized here

only because single-case experimental research in behavior modification has embraced a therapeutic criterion as a central feature of treatment evaluation.

Generality of the Results

An important issue, often noted in the form of an objection to single-case experimental designs, is that the results from an individual case may not necessarily apply or be generalizable to other subjects.⁴ The generality of experimental findings in between-group and single-case research is a weighty topic that cannot be developed fully here (see Hersen & Barlow, 1976; Kazdin, 1973). Suffice it to say that mere numbers of subjects do not, in their own right, guarantee generality of the results. Indeed, the vast majority of between-group investigations evaluates results on the basis of average (mean) group performance, which does not provide insights about the generality of a particular effect within a given experimental condition. Yet, this latter problem is a function of not looking at all of the individual subject data within a between-group investigation. With single-case demonstrations, there is no immediate possibility to assess generality, by definition.

Although it is quite possible that the effects of treatment demonstrated with the individual case may not generalize to others, this does not appear to be a problem in contemporary research. Findings obtained in single-case demonstrations appear to be as generalizable, if not much more so, than demonstrations using other designs. The reason for this does not seem to be related to the designs per se but rather to the type of interventions that are commonly evaluated. Investigators who use single-case designs have made a special point to look for interventions that produce dramatic changes in behavior. Interventions with such effects for the single case are likely to generalize more broadly than are interventions that meet the relatively weaker criterion of statistical significance based on group averages that characterize between-group research.

Although generality of the results in single-case designs is not an inherent problem, investigation of the dimensions along which

generality might occur is difficult. The designs characteristically are weak in revealing subject characteristics that may interact with a specific treatment. Focusing on one subject does not allow for the systematic comparison of different treatments across multiple subjects who differ in various characteristics, at least within a single experiment. Examination of subject variables is more readily accomplished by between-group research, specifically, factorial designs in which intervention effects can be analyzed separately according to characteristics of the subjects. Yet, single-case experiments have focused on developing potent interventions that tend not to depend heavily on subject characteristics. This has been a matter of philosophy rather than a simple design consideration (Kazdin, 1978a). The ultimate test of generality of findings among subjects or any other condition is replication. Single-case experiments commonly replicate intervention effects across a wide range of clients (e.g., Kazdin, 1977d).

Concluding Comments

Single-case experimental designs offer unique advantages for research in clinical psychology because they provide an empirical and scientific basis for investigating interventions with individual clients. The diverse designs permit examination of different outcome questions, such as the effects of an overall treatment package, analysis of components of a package, and comparison of different treatments. Single-case designs make available areas not easily studied in group research. For example, many clinical problems cannot be studied on a group basis simply because few clients come for treatment or the behaviors are extremely rare.

Single-case designs make demands on an investigator that may not be easily met in many clinical situations. Initially, client behavior needs to be observed continuously, a task

⁴ It is only fair to point out that many "single-case" designs utilize more than one individual; indeed, large groups often are included in such designs. Also, some design variations including one of the multiple-baseline designs routinely rely on more than one individual.

more difficult to implement than traditional pretreatment and posttreatment assessment. Second, behavioral measures usually are constructed to assess the individual client's problem. Third, some designs require reinstating conditions that compete with effecting durable therapeutic changes. Finally, many important questions are not easily addressed, such as the interaction of client, therapist, or setting variables with the intervention. Interactions of this sort are more readily addressed in group factorial designs.

Single-case designs appear relatively straightforward, a characteristic that may foster rather than ameliorate the methodological and interpretive problems highlighted in this article. Complexities of the designs derive from the lack of clear rules for deciding how long to gather data, when to implement treatment, and the criteria for evaluating change. Quantitative guides for making decisions about changing from baseline to intervention phases and for evaluating the statistical reliability of interventions are available but are still infrequently used in the literature. The best guide for appropriate use and interpretation of single-case experiments is recognition of the basic logic of the designs and common methodological problems. The present article addressed some of the major problems that impede interpretation of findings with single-case experiments.

Stimulus Sampling in Clinical Research: Representative Design Reviewed

Brendan A. Maher
Harvard University

Brunswik's concept of representative design is reviewed with special reference to studies of clinical bias. The limitations of single-stimulus, actor-script, and serial replications are discussed. No satisfactory alternatives exist to adequate sampling of stimulus persons.

More than 30 years ago, Egon Brunswik (1947) pointed out that if we wish to generalize the results of a psychological experiment to populations of subjects and to populations of stimuli, we must sample from both populations. This argument was elaborated by him in other articles and was summarized cogently in a short article by Hammond (1948). The purpose of this article is to review the issues that Brunswik raised and to examine some of their implications for contemporary research in clinical psychology.

Brunswik's thesis is very simple. When we conduct an experiment intended to investigate the effect of different values of an independent variable on a population, we always take care to draw a sample of subjects that is representative of the population in question. We do so, naturally, because we recognize the range of variation that exists in populations of individuals. We wish to make sure that deviant individual values do not distort our estimate of the parameters of the population. If the stimuli that we use are defined in physical units, we are (or should be) careful to confine our generalizations to the range of values actually included in the study. When physical units are involved, we have relative confidence that the stimulus can be replicated by another investigator, provided that the detailed descrip-

tion of the stimulus is followed carefully. Should a subsequent investigator change one or more of these attributes, we are not surprised if there is a concomitant change in the responses that are made to the stimulus.

When the stimuli to which the subjects respond cannot be defined in physical units and are likely to vary within a population, a different situation arises. Outstanding examples are to be seen in research directed to the investigation of the effects of human beings as stimuli that elicit behavior from other human beings. Consider some instances drawn from recent volumes of this journal. Acosta and Sheehan (1976) reported that Mexican American subjects viewed an Anglo American professional therapist as more competent than a Mexican American professional when all other variables were matched. Babad, Mann, and Mar-Hayim (1975) reported that trainee clinicians who were told that a testee was a high-achieving upper-middle class child assigned higher scores to Wechsler Intelligence Scale for Children (WISC) responses than did another sample of clinicians who were led to believe that the same responses had been made by an underachieving deprived child. Research of this kind is generally cast in terms of a hypothesis that members of a specified population respond in discriminatory fashion to members of certain other populations. Thus, for example, we encounter such questions as, Do physicians give less adequate medical care to ex-mental patients than they do to normal medical patients? (Farina, Hagelauer, & Holzberg, 1976) and Are thera-

My appreciation is due to Winifred Barbara Maher for her critical reading of early drafts of this article. Requests for reprints should be sent to Brendan A. Maher, Department of Psychology and Social Relations, Harvard University, Cambridge, Massachusetts 02138.

pists with a behavioral orientation less affected by the label *patient* when evaluating observed behavior than are therapists of psychodynamic persuasion? (Langer & Abelson, 1974).

Single-Stimulus Design

Human attributes are generally distributed in such a fashion that any one of them is likely to be found in conjunction with a wide variety of others. Let us consider an investigation of bias toward ex-mental patients. To belabor the obvious a little, we can note that the attribute *ex-mental patient* can be associated with any measure of intelligence, age, sex, education, socioeconomic status, physical attractiveness, and so forth. It is true that some of these attributes may have significant correlations with each other; a patient of upper socioeconomic status is quite likely to have had substantial education, for example. Nonetheless, even the largest of these correlations is quite modest, and the population of ex-mental patients to which we wish to generalize will have a wide range of values on these attributes.

When we employ only one person as a stimulus, we are faced with the fact that the specific values of some of the other attributes possessed by this person will also have stimulus value that will be unknown and uncontrolled. Responses made by a sample of the normal population to an ex-mental patient who is female, young, attractive, articulate, and intelligent may well be different from those made to a normal control who is male, old, ugly, incoherent, and dull. These differences cannot be assigned to the patient/non-patient status of the two stimulus persons, as many other unidentified differences were uncontrolled. At first sight it may appear that this problem is solved by the simple expedient of matching the patient and the control on all variables other than that of patient status. Unfortunately, this can only be achieved at the cost of further difficulties. We do not know the full range of variables that should be matched, and hence this solution necessarily involves resort to an actor and a script, barring the unlikely availability of discordant monozygotic twins for research purposes! Scripts bring with them some special prob-

lems, of which more will be said later. The main point to note here is that the use of a *single* human stimulus acting as his or her own control fails to deal with the problem of the *interaction* of the attribute under investigation with those that have been controlled by matching. Pursuing for a moment the example of responses to the label *ex-mental patient*, let us consider a hypothetical study using a male actor with athletic physique and vigorous movements. The willingness of a normal subject to accept this individual as a fellow worker, neighbor, or friend may well be influenced by the perception that the ex-patient, if violent, could be dangerous. Had the actor been older and visibly frail, the reaction might well be different. Under the first set of circumstances, the bias hypothesis would probably be confirmed, and under the second set, the null hypothesis might fail to be rejected.

An additional difficulty is incurred by the single-stimulus own-control strategy. We cannot determine whether a finding of no difference between group means is due to the weakness of the hypothesis, errors of method, or the inadvertent selection of an atypical stimulus person to represent one or both conditions. An example of the complexities of interpretation with this design can be found in Farina et al. (1976). These investigators hypothesized that physicians would provide less adequate medical care to former mental patients than to normal medical students. To test this hypothesis one stimulus person, a 23-year-old male graduate student, approached 32 medical practitioners. In each case he entered the doctor's office

carrying a motorcycle helmet and a small knapsack. . . . The same symptoms were reported to all doctors. Stomach pains suggestive of ulcers were selected to be neither clearly psychiatric nor unrelated to the mind. . . . Every other practitioner was told the pains had first occurred 9 months earlier while the patient was traveling around the country. The remaining 16 doctors were also informed that the pains had appeared 9 months earlier, but at that time the patient reported being in a mental hospital. (Farina et al., 1976, p. 499)

No significant difference of any relevance was found in the kind of medical care given by the practitioners under either condition. In

conclusion, the authors stated that "a former mental patient seems to receive the same medical treatment as anyone else" (p. 499).

Logically, several conclusions are compatible with this finding. One obviously valid conclusion is that a young male motorcyclist with the symptoms of ulcers receives a certain class of treatment whether or not he describes himself as a former mental patient. We cannot tell whether this treatment is the same, better, or worse than that typically given to a random sample of the normal population of patients who seek treatment for stomach pains, as no such sample was obtained. A substantial number of physicians may have had opinions about motorcyclists as unfavorable as those that they were hypothesized to have about former mental patients, and hence both conditions produced equally inadequate medical care. Alternatively, the physicians may have felt the necessity to be unusually careful in providing care to individuals who might be assumed to be irresponsible (such as motorcyclists and mental patients), and hence they provided better than average care. Finally, medical practice may be sufficiently precise that the adequate procedures to follow with patients who complain of stomach pains that no real room for bias exists, the treatment provided being the same as would be given to any sample of patients.

We can summarize the limitations of the single-stimulus design as follows:

1. Obtained differences may be due to the validity of the tested hypothesis or to the effect of uncontrolled stimulus variables in statistical interaction with the intended independent variable. No method of distinguishing between these two explanations is possible.

2. Lack of difference may be due to the invalidity of the hypothesis, undiscovered methodological factors such as subject sampling error, or the presence of an uncontrolled stimulus variable operating to either counteract or raise this effect to a ceiling value in both experimental and control situations.

It is readily apparent that the problem of uncontrolled attributes occurring in a single stimulus person can only be solved by the provision of an adequate sample of stimulus persons, since they will tend to cancel each

other out. No satisfactory solution is possible within the single-stimulus design.

Scripts and Manticores

Some investigators have attempted to solve the problems of the single-subject stimulus by fabricating scripts without the use of a human actor to present them. Case histories, dossiers, vignettes, audiotapes, or other devices have been used to reduce the effects of the uncontrolled aspects of a human stimulus. Thus, in a study by Babad et al. (1975), the trainee clinicians were given only the WISC protocol and did not see the child who was alleged to have been tested. These manufactured materials may be termed *scripts*. Scripts may be taken from existing sources of genuine material, such as clinical files; they may be created de novo in accordance with prior theoretical guidelines or in an attempt to present an ideal "typical" case.

When the script is drawn from original clinical files, the investigator is assured that at least one such case exists in nature. The limitations on the results obtained from such scripts are, in principle, the same as those that plague any single-stimulus design. Some minor advantage accrues to the method, however, in that the number of uncontrolled accidental attributes has been reduced by the elimination of those attributes associated with physical appearance, dress, and so forth. When the script is fabricated for research purposes, a new problem develops—namely that in devising material according to theoretical guidelines, a case is created that like the manticore, may never have existed in nature. We can imagine a hypothetical investigation of the attitudes of males toward females of varying degrees of power. Varying naval ranks with male and female gender of the occupant of each rank, we create the dossier of an imaginary female Fleet Admiral. Whatever our male subject's response to this dossier may be, we have no way of knowing whether it is due to the theoretically important combination of high rank with female gender or to the singularity of a combination that is, as yet, unknown to human experience.

For a recent illustration of this problem, we can turn to Acosta and Sheehan (1976). They

presented groups of Mexican American and Anglo American undergraduates with a videotaped excerpt of enacted psychotherapy. Each group saw an identical tape, except that in one version the therapist spoke English with a slight Spanish accent and in the other version the accent was standard American English. Some subjects were told that the therapist was a highly trained professional; the others were told that the therapist was a paraprofessional of limited experience. There were thus four experimental conditions and two kinds of subjects. The Spanish-accent tape of a trained professional was introduced with a background vinette describing the therapist as American born of Mexican parentage and as having a Harvard doctorate in his field and a distinguished professional record. For the American-English-accent tape, the therapist was introduced with the same vinette but with an Anglo-Saxon name and parentage identified as Northern European. Anglo American ratings of the therapist's competence were uninfluenced by the ethnic identification, whereas Mexican Americans rated the Mexican American therapist less favorably than the Anglo American therapist.

In their discussion of this somewhat surprising result, the authors noted that the number of Mexican American therapists actually in practice in the United States shortly before the study was done was 48 (28 psychologists and 20 psychiatrists). We do not know what characteristics would be typical of this population, and no attempt seems to have been made to ascertain them before preparing the script. There is, therefore, no way to be sure that the therapeutic style, choice of words, gesture, and so forth, were authentically typical of actual Mexican American therapists. Given that essentially the same script was used for both ethnic conditions, we must conclude that either one or the other version of the script was ethnically inaccurate or, less likely, that the only actual difference that would be seen in the comparative behaviors of Mexican American and Anglo American therapists would be their accent. In brief, we cannot ignore the possibility that the Mexican American subjects disapproved of the Mexican American therapist not because he was Mexican American but because his behavior was not representative of that of actual Mexican

Americans. Like the woman admiral, he may have presented a combination of characteristics that is theoretically possible but unknown in the experience of the subjects responding to it. The only guarantee that a script is free from impossible or improbable combinations of variables is when it is directly drawn from an actual clinical case or other human transaction. We cannot produce a fictional script of a psychotherapeutic session with any confidence that it is as representative as a transcript of an actual session. The ideal or typical therapeutic interview may be as rare as the perfect textbook case of conversion hysteria or as a stereotypical Mexican American. This rarity or implausibility may well determine a subject's response far more than the attributes that were planned to make it appear typical. Our hesitation in generalizing from a single stimulus case to a population of cases is increased substantially by the prospect of generalizing from a case that is not known to have existed at all.

Representative Design

The moral to the foregoing review is simple. If we wish to generalize to populations of stimuli, we must sample from them. Only in this way can we be confident that the various attributes that are found in the population will be properly represented in the sample. Those attributes that are significantly correlated with membership in the population will appear in appropriate and better-than-chance proportions; those attributes that are uncorrelated with population membership will appear in chance proportions but will not affect the outcomes. If we intend to draw conclusions about the way in which physicians treat former mental patients, we must sample physicians and former mental patients. If we wish to know what Mexican American students think of Mexican American therapists, we must sample students and therapists. This is the essence of Brunswik's (1947) concept of representative design. There is no satisfactory alternative to it. Nonetheless, the use of representative design is rarely, if ever, seen in reported research. There are, in my opinion, three reasons for this. First, many clinical psychologists are unaware of Brunswik's work. The remedy for this is obvious and easy to

apply. Second, there is a common failure to understand that the replication of single-stimulus studies with additional single-stimulus studies cannot create accumulated representative design unless the selection of single-stimulus persons was achieved by sampling.

Let us consider a hypothetical series of studies of the effect of examiner gender on children's test responses. In the population of examiners, there are likely to be attributes that distinguish males from females in addition to those that are inseparable from gender. Thus the proportions of married and single persons, prior experience with children, knowledge of various hobbies, mean age, prior locale of undergraduate education, and so forth, may differ between the two groups. In the first study we use one male examiner and one female examiner, each with 1 year of experience. Using samples of male and female children, we find differences in test responses attributable to examiner gender. Conscious of the fact that we included inexperienced examiners, we replicate the study with one male examiner and one female examiner each with 3 years of experience. Now we find no difference. Our series ends when we have made gender comparisons for examiners with 1, 3, 5, 7, 9, 11, 13, 15, 17, and 19 years of experience. We found significant examiner effects at every level of experience except 3 and 5 years. As 8 of our 10 studies have found significant differences due to gender, we conclude that there is a generalizable finding. We might even treat the entire series as a single experiment comparing the group of 10 male examiners with the group of 10 female examiners and find a statistically significant difference between the mean test responses elicited by one group versus the other.

To accept this conclusion it is first necessary to know what the true proportion of the total population of examiners at each level of experience is. If the experience range of 3-5 years includes 65% of all examiners, our best conclusion is that gender differences have not been established. The reason is, of course, that the "sample" of examiners was not representative of the population to which it is intended to generalize, being underrepresented in the 3- to 5-year experience range. Note that we cannot handle this by some proportional weighing of the data obtained from the ex-

aminers with 3-5 years of experience, as the results obtained from those comparisons suffer from the limitations of single-stimulus design and might well be due to the effects of uncontrolled differences between examiners other than gender.

A third reason for the failure to use representative design is that it is laborious and expensive. Providing an adequate sample of stimulus persons, each of whom is to be observed by an adequate sample of subjects, necessarily involves large numbers and long hours. For some investigators it is, as one of my correspondents put it, "too hard to do it right."

There is, however, no satisfactory alternative to doing it right. Clinical psychology is concerned with real people and not with hypothetical collections of attributes. Our research into the behavior of patients, therapists, diagnosticians, normal persons, and the like, must produce generalizations that are valid for actual populations of these people. Conclusions based on inadequate sampling may be worse than no conclusions at all if we decide to base our clinical decisions on them. If the patience and time that it takes to do it right create better science, our gratitude should not be diminished by the probability that fewer publications will be produced.

Common Methodological Problems in Factor Analytic Studies

Andrew L. Comrey
University of California, Los Angeles

Investigators are urged to plan factor analytic studies prior to collecting the data, to formulate a hypothesized factor structure, to develop several relatively pure measures of each factor expected, and to select an appropriate sample of at least 200 cases. Continuous variables should be used rather than dichotomous variables wherever possible. Programmatic series of studies are preferred over one-shot investigations. Putting unities in the diagonals and rotating all factors with eigenvalues of one or more is discouraged, because this procedure tends to give communalities that are too high, produces too many factors, and distorts the rotational solution, especially when analytic rotational programs are used. In some situations, a computer-assisted hand rotational solution is most likely to give satisfactory results. Mathematical algorithms designed to approximate simple structure work well only in situations properly designed for their application.

Despite the fact that factor analysis has been roundly condemned by many behavioral scientists as being without redeeming social or scientific value, the number of factor analytic investigations reaching manuscript form appears to be on a geometric upward course. Why? For one thing, critics of factor analysis often are not sufficiently knowledgeable about factor analysis to discriminate between a proper and an improper use of the technique. They are ready, therefore, to generalize from a collection of poor studies to the conclusion that all factor analytic studies are worthless. There are situations in which benefits can be derived from the proper use of factor analysis, and this fact can account at least to some extent for its expanded use despite persistent and heavy criticism. Probably a greater reason for the increase in use, however, is the ready availability of programs at various computer centers that will produce factor analytic results cheaply. The temptation to use such a convenient resource in this publish-or-perish age is apparently overwhelming. If all else fails in dealing with a body of data, there is

always the computer and factor analysis standing ready to rescue an otherwise fruitless quest for publishable results. In the face of an avalanche of poor factor analytic studies, it is not surprising that many thoughtful scientists and journal editors have come to distrust the method. For those who are willing to take the trouble to learn how to use such methods properly, however, factor analysis can serve as a powerful analytic tool to aid the scientist in his search for reliable knowledge. The purpose of this article is to warn inexperienced users about some of the pitfalls that they may encounter in trying to use factor analytic methods in their research.

Design of Factor Analytic Investigations

In experimental studies it is rather unlikely that a statistical treatment procedure can be found after the data have been collected that will be entirely satisfactory unless some thought was given to the analysis when the study was designed. It is obviously best to design the data collection for use with a particular method of statistical analysis. So it is with factor analysis, too. The variables should be selected with some particular theory or conceptual framework in mind, the data should be collected in such a way that appropriate

Requests for reprints should be sent to Andrew L. Comrey, Department of Psychology, University of California, Los Angeles, California 90024.

correlational methods can be used, and a suitable sample of individuals should be selected that will allow for appropriate application of the chosen method of analysis. Unfortunately, all too often, factor analysis is thought of only after the data are already in. At this point, it may be next to impossible to carry out a good factor analytic investigation.

The moral of the story, therefore, is to plan ahead when using factor analysis. The investigator should start with a first-stage conception of what the factor structure should be like in the domain he is studying (Guilford & Hoepfner, 1971; Thurstone, 1947). This first-stage conception may be generated by theory, intuition, past results, or a combination of these elements. The fact that an investigator should start with a tentative conception of what the ultimate factor structure is apt to be does not mean, of course, that he should try to force the results to confirm that original conception. He should at all times be alert to evidence that the data poorly confirm that conception and take steps to revise it accordingly.

Variables should be selected for the analysis that will provide good representative measures for each of the expected factors. Insofar as possible, it is preferable to have variables that will measure one and only one of the expected factors in any substantial way. Complex variables that measure several different factors will be of little value in locating the proper factor structure in the analysis. After the variables have been selected, it is important to develop good measures of these variables that will produce reliable scores with adequate continuous distributions in the sample of individuals to be studied. Without good continuous measures, the correlation matrix to be factor analyzed will be a poor one. Finally, the sample must be carefully selected to be representative of the kind of population to which the investigator wishes to generalize his results. It also must be large enough to give stable correlation coefficients. If possible, there should be at least five times as many variables as the number of expected factors, and there should be a least 200 subjects. I have found continued reduction in the perturbation in factor analytic results up to samples of 2,000 cases before the factor struc-

ture stabilized. Factor analytic results based on small samples can be considered at best as crude hypotheses to be tested in further investigations.

Beyond planning ahead in designing a factor analysis, it is important to understand that the best use of factor analysis takes place in a programmatic series of investigations in which the researcher is constantly refining his conception of the factor structure and the variables that represent the factors, improving the extent to which the variables measure the factors, and testing hypotheses in subsequent studies generated by results in prior investigations. A hypothetico-deductive approach is recommended. The initial investigation gives a first approximation to what the factor structure should be. On the basis of this conception, modifications in existing variables are made, new variables are added, and so on, and predictions are made about what will happen in the next study as a result of these changes. The next study verifies or fails to verify these predictions, thereby generating further suggested changes. In this manner, the researcher gradually clarifies what the factors are in a given domain and what variables measure them in the most effective way. His results are stabilized over a series of investigations using different samples.

This is not to say that a one-shot, after-the-fact treatment of existing data using factor analysis in a hunting expedition is always useless. Such results are useful, however, mainly as hypotheses to be followed up by more adequate programmatic research. In and of themselves, they have little value from a scientific standpoint unless they can be verified in other investigations. It should also be emphasized that good programmatic factor analytic research usually will not be sufficient in and of itself to establish the ultimate utility of the identifying factors. Internal analysis of correlational data usually must be supplemented by experimental and other kinds of non-factor-analytic investigations to test hypotheses related to the factors before their scientific value can be clearly demonstrated.

Selection of the Sample

The particular sample of individuals studied in a factor analytic investigation can have a

profound effect on the outcome of the analysis. If we give ability tests to a sample of children ranging in age from 8 to 14, for example, a huge general factor may be generated, since most of the 14-year-olds will probably do better than most of the 8-year-olds on all the tests. The correlations between all tests will be very high, and a single factor will account for most of the variance. An unwary investigator might call this a general intelligence factor, but in reality it is only a maturation factor. If all the tests were to correlate substantially within a sample of children of the approximate *same age*, on the other hand, this would be indicative of a general intelligence factor running through these cognitive measures. If, however, students from a very selective educational institution of higher learning were given tests of a similar kind, the general factor might disappear entirely because variance would be so restricted on general intelligence. Since all of the students would be very bright in such a sample, the general factor would be lost, leaving only group factors.

It is very important to avoid idiosyncratic collections of subjects that can have gross effects on the correlation matrix. For example, if two subjects who have much higher (or lower) scores than all of the other subjects on several of the variables are in the same sample, this will greatly elongate the scatter plot ellipses, generating very high correlations for those pairs of variables and injecting a great deal of spurious common factor variance into the matrix. The investigator cannot necessarily anticipate all of the special circumstances that might give him spurious results. He can be suspicious, however, of any unexpectedly high correlations, or low ones for that matter, and investigate thoroughly to determine if there are special problems with his data leading to distortions in the correlation coefficients.

Selection of the Variables

It has already been indicated that a preliminary conception of the probable factor structure in the domain under investigation should be formulated, and then variables should be selected for the analysis that will

provide good definitions of these putative factors. Ideally, a variable for a factor analytic study should measure one and only one factor in the domain to any substantial degree; that is, it should be a pure-factor measure. This is not usually possible for all of the variables in the matrix, since it is difficult to develop pure-factor measures. In particular, it is not likely to be the case when the investigator is bound to use existing data that were not collected with a factor analysis in mind. When the analysis is planned in advance, the investigator can and should carefully plan which variables he wishes to include, selecting approximately an equal number of variables for each hypothesized factor and trying to make each variable as pure a measure of one factor as he can. He should seek particularly to avoid the situation in which a substantial percentage of the included variables are complex measures, each with substantial expected contributions to two or more factors. It is very difficult, if not impossible, to attain an appropriate rotational solution with any known analytic method when a majority of the variables in the analysis are complex.

Beyond getting the most appropriate collection of variables in the matrix, it is very important to develop good, reliable measures of those variables. All too often, there is an attempt made to factor analyze poor data variables, such as two-choice questionnaire items with poor splits in the proportion of yes and no responses. Proper variables for factor analytic purposes should be relatively continuous; that is, they should have many possible categories of response and reasonably normal distributions. Also, the regressions for every pair of variables should be linear and reasonably free of gross departures from the normal expected elliptical pattern of data points in the scatter diagram. When two-choice response variables are used, it is not even possible to investigate linearity, and furthermore severe distortion can be introduced into the correlation matrix with a consequent dramatic effect on the factor analytic solution. If one variable is represented by a measure that splits 50-50 while another is represented by a measure that splits 95-5, the maximum possible correlation between the two variables is limited to an absolute value of

approximately .23. With more appropriate measures on continuous scales, these two variables might correlate much higher. The form of measurement of these two variables imposes an artificial limit on the size of the correlation that could introduce a serious distortion in the obtained factor structure.

Even more dramatic distortions may occur, however, because grossly inflated correlation values also can be introduced by poor measures of the variables used. Again using two-choice variables as an illustration, suppose that in a sample of 200 cases, 199 subjects answered no to two items and one person answered yes to both. In this case, the correlation between the two variables would be 1.00 because of 1 deviant individual out of 200. If that person had said no to both items, the correlation would have been .00 instead of 1.00. Thus, with two-choice data, the correlations can be artificially limited in size or they can be grossly inflated, depending on the situation encountered, as compared with what probably would have occurred with continuously measured, normally distributed variables. The investigator, therefore, should seek to use variables for analysis that are continuous rather than dichotomous. I have personally given up using two-choice items wherever possible, preferring to work with seven-choice items if they are to be factor analyzed. This substantially reduces the possibility of gross distortions in the correlations like those indicated above. Beyond this, in factor analytic studies with taxonomic objectives, I prefer to use variables that are total scores summed over several homogeneous items that have been shown to be measuring the same variable. These total scores have many more possible data points than the seven associated with a single item. Such scores are more continuous, tend to be more normally distributed, and are almost always more reliable than individual item scores. Factor analytic results for such improved measures are much less subject to distortion than those based on dichotomous measures from single items.

Attempts have been made to correct for errors in two-choice variable intercorrelations by using such devices as phi over phi max and tetrachoric correlations, but these methods even theoretically only deal with the

problem of artificial limits on the size of the correlations. These methods do not even address the problem of spuriously high correlations. Comparisons of the results of factor analyses of the same data using phi coefficients (Pearson correlations with 1 and 0 values assigned to the two dichotomous categories), phi over phi max, and tetrachoric correlations show that the latter two coefficients can grossly inflate the amount of common factor variance in the matrix in certain situations (Comrey & Levonian, 1958). The sad fact is that nothing can be done to make good data out of poor data. Wherever possible, the investigator should make plans in advance to obtain continuously measured scores for the variables that he wishes to factor analyze. If dichotomous measures must be used, try to get them as close to 50-50 splits as possible for all measures and then interpret the results very cautiously. In particular, look for any large correlations that might have been artificially elevated by idiosyncratic response distributions in the measures correlated.

Extraction of Factors

What to put in the diagonal cells as initial communalities and how many factors to extract are the two decisions that create the most difficulty for typical research users of factor analysis. Many popular computer programs offer the option of inserting 1.0 for each communality (diagonal) cell of the correlation matrix followed by the extraction of all factors by the principal factor method that have eigenvalues greater than or equal to 1.0 (called the "eigenvalue-one criterion" by Rummel, 1970, p. 363). That is, the sum of the squares of all factor loadings for the extracted factor is 1.0 or greater. One justification for this procedure is that each variable included in the matrix adds 1.0 to the total communality in the entire matrix, hence any retained extracted factor should contribute at least as much as the effect of adding one variable to the matrix. This option has become very popular, probably because it is readily available in existing computer programs that are widely used, and because it requires no judgment on the part of the investigator.

There are problems with this approach, however, that can lead the unwary investigator astray (Comrey, 1973; Guertin & Bailey, 1970; Lee & Comrey, Note 1; Comrey & Lee, Note 2). First of all, each variable has 1.0 as its potential communality after all possible factors have been extracted. This is true whether the variable has much or little actual common factor variance. By the time all factors have been extracted with eigenvalues greater than 1.0, it not infrequently happens that an amount of common factor variance has been extracted for certain variables that is inappropriately high given the size of the correlations with the other variables in the matrix. This is particularly apt to occur when items of a two-choice nature are being correlated. These variables are notoriously unreliable and often have low correlations with each other. The factor results based on analysis of such matrices with the eigenvalue-one procedure described above, however, often show very high communalities and large factor loadings for these dichotomous variables. When this spurious extra common factor variance is introduced into the matrix, the number of factors that seem worthy of retention even after rotation, is often too high, further distorting the solution. It is my conclusion that the eigenvalue-one procedure should not be used unless the variables in the matrix are all good, reliable, continuous measures that correlate substantially with each other, leading to rather high true communalities for all variables. In this case, the distortion introduced by the eigenvalue-one procedure is less likely to represent a problem.

The distortion introduced by this method can be mitigated by iterating the communalities, that is, after extracting factors with eigenvalues greater than or equal to 1.0, reinsert the accumulated communalities for that number of factors, reextract the same number of factors, and repeat (Lee & Comrey, Note 1; Comrey & Lee, Note 2). Unfortunately, the values to which the communalities converge, if they do, will not necessarily and often will not be, the same values to which they would converge starting from different initial communality estimates. If unities are used in the diagonals to begin with for a common factor analysis, however, I believe that it is better to

iterate the communalities to stability, since this will typically introduce less distortion into the solution than failing to iterate.

It cannot be assumed, however, that the correct number of factors is obtained by stopping extraction when the eigenvalues are less than 1.0. This procedure would seldom give too few factors, although it often gives too many. The investigator should look at a number of criteria for terminating extraction, including examining rotated solutions with different numbers of factors, before leaping to the conclusion that he has the right number. There is no definitive solution to the problem of determining the correct number of factors. It is up to the investigator to use all of the information that he can get to reach a conclusion about this and to try to justify his conclusion within several converging lines of evidence instead of relying on a universal rule of thumb.

A second common factor extraction strategy is to use squared multiple correlations in the diagonal cells and extract all factors by the principal factor method having eigenvalues greater than zero. This procedure can be followed by iteration of the communalities until they stabilize. The stabilized communalities generally will not diverge from the squared multiple correlations by this procedure as much as the stabilized communalities will differ from 1.0 in the previously discussed procedure. For this reason, iteration of the communalities is less necessary in this latter procedure, and in fact, it may not give a better solution than the noniterated communalities. Iteration of the communalities tends to increase the size of these values, on the average, capitalizing on chance error to raise the proportion of variance extracted. I have found cases in which it appears that the communalities have been raised to unrealistically high values by this iterative process (Comrey, 1973). It is not unreasonable, however, to iterate the communalities and examine the results in comparison with the uniterated results to see which solution can be justified as being the more reasonable. The number of factors must be kept constant during the iteration process, however, or the number of factors will gravitate toward the number of variables and the communalities will gravitate toward 1.0

instead of stabilizing at smaller values. Using squared multiple correlations and eigenvalues greater than zero as a criterion will typically extract substantially more factors than the eigenvalue-one procedure. Care must be taken to eliminate superfluous factors during the rotation process to avoid distorting the final solution.

A third alternative factor extraction strategy is to obtain a solution that does not require communality estimates. Comrey (1962) and Comrey and Ahumada (1964) have proposed a stepwise minimum residual solution that operates only on the off-diagonal elements of the correlation matrix. Communalities are derived as a result of the factor extraction process rather than being estimated ahead of time and then influencing the calculation of factor loadings. The Comrey and Ahumada procedure has a built-in criterion for terminating extraction when iterated factor vectors converge on vectors of opposite sign in the extraction process. This corresponds roughly to the point in the principal factor method of terminating factor extraction where eigenvalues become negative when squared multiple correlations have been used as initial communality estimates. The communalities that result from this minimum residual procedure can be used as the point of departure for an iteration of communalities by the principal factor method. This may or may not prove to be defensible, depending on the degree of elevation of the communalities by the iterative process. Iterating the communalities, starting with the minimum residual solution communalities as initial estimates, appears to give about the same results in most cases that would be obtained for that number of factors using the Harman and Jones (1966) minres method. Minres is also a type of minimum residual solution that reduces the off-diagonal residuals to a minimum, but it does so after a specified number of factors, not one at a time as in the Comrey (1962) method. With the minres method, the number of factors desired must be specified in advance.

Thus, extracting factors by the principal factor method with squared multiple correlations in the diagonal and iterating until communalities stabilize, extracting factors by the

Harman and Jones (1966) minres method, or extracting factors by the Comrey method (1962) and iterating the communalities all give similar results if the number of factors is held constant. Extracting the same number of factors with the communalities set equal to 1.0 can give very different results that are difficult to defend. If the eigenvalue-one results are iterated until the communalities stabilize, the amount of distortion will typically be lessened although not necessarily eliminated entirely. Determining the number of factors to extract is still a major problem with all of these methods. Ordinarily, it is necessary to consider a variety of criteria and even rotate various numbers of factors before coming to a final conclusion about what is the appropriate number of factors. Just accepting the number of factors suggested by a particular termination criterion can lead to gross distortions in the final results.

Many other procedures for extracting factors are available, each with its own characteristics and potential abuses.¹

Rotation of Factors

The unrotated factor matrix is computed in most methods such that the product of this matrix by its transpose will approximate the original correlation matrix within a certain margin of error. If a given factor matrix will do this, so will an orthogonal transform of that matrix, that is, a matrix that can be reached by orthogonal rotations of the unrotated factors. The axes do not even have to be rotated orthogonally, but then the angles formed by the axes must be considered in reproducing the correlation matrix. The various methods of factor extraction obtain the unrotated matrix by satisfying certain mathematical criteria, such as extracting the maximum amount of variance in one factor or minimizing the sum of squares of residuals of off-diagonal elements, and so on. In almost all cases, these mathematical criteria locate the factor axes in positions that have nothing to do with psychological meaningful positions for the axes. In these cases it is necessary,

¹ For further information, consult the factor analysis textbooks mentioned later in the article.

therefore, to carry out rotations of the unrotated factor axes, either orthogonal or oblique, before the factor axes are appropriately located to define psychologically meaningful constructs. Since the number of different positions for these axes is virtually unlimited, there is no unique solution to the rotation problem in factor analysis. Many different criteria have been developed to help the investigator locate the "correct" factor axis positions, but none of these criteria has achieved general acceptance. The basic reason for this is that no one criterion of rotation *can* fit all situations, since the proper location of axes in a given matrix is often quite specific to that particular problem. A rotational solution is nothing more than the investigator's interpretation of the data. It may or may not be a good one.

Thurstone (1947) popularized the criterion of simple structure for rotation of factor axes, and many of the modern computer procedures for rotation of axes are merely attempts to approximate simple structure through the application of specially designed mathematical algorithms to the data. Simple structure usually will work reasonably well, as will computerized approximations to it, if the study is properly designed for the use of this criterion. Thus, if there are several well-defined factors, each measured by several pure-factor measures (one-factor variables) that are normally distributed and reliably assessed, and if there are few if any complex factor measures, simple structure will ordinarily work very well indeed. Unfortunately, in practice relatively few factor analytic studies carried out actually fit this model. In most actual analyses, the factors are not so well charted in advance, each factor does not have several pure-factor measures to define it, and there are usually many complex variables. The number of variables per factor may vary considerably, and often there are too few well-defined factors in the matrix.

When the factor matrix being analyzed falls into this latter category, simple structure is not apt to be very successful in pointing the way to the best solution of the rotation problem, and of course no computer algorithm designed to approximate simple structure will either. A problem such as this requires all of

the skill and experience that the most knowledgeable factor analyst can muster to have any hope of locating the best solution. Since such idiosyncratic collections of variables do not fit the simple structure paradigm, to locate the best factor structure for the data it is often necessary for the investigator to fix the rotated factor positions in accordance with knowledge that he may have about the variables. Thus, he might know that one variable has been found in several past analyses to be a relatively pure measure of a certain factor. In his rotations, he would deliberately place one of the factors coincident with this variable vector and attempt to rotate it in such a way that variance for this variable would not appear in any substantial way on other factors. He might know that two other highly correlated variables were complex composites of factors X and Y. Not having pure measures of X and Y, positioning of the axes would be difficult, but at least the factors could be positioned in such a way that a factor is not run through these two complex variables as an analytic rotation program might. In short, a resort to the old "hand-rotation" procedures using all of the knowledge that one can muster about the variables may be necessary to have any chance of getting a reasonable rotated factor solution (Comrey, 1973). This skill has almost become a lost art with the advent of the high-speed computer. These hand rotations can be performed without undue labor, however, using the computer to do the hard work, so there is no need to give up this valuable option just because it used to be so laborious.

I have developed a computer program (Comrey, 1973), for example, that first plots the factors. These plots are inspected visually to find the desired rotation, orthogonal or oblique, and then the instructions are given to the computer to carry out the rotations and make new plots. The investigator only has to inspect the plots and determine which factors he wishes to rotate by which angles of rotation. This is more work than applying a computer-programmed analytic method, of course, and it requires the application of some judgment, but it is not laborious, and it is a skill that can be mastered with some practice.

Critics of factor analysis will be quick to

point out that such a procedure is subjective and hence suspect. This is no doubt true. The investigator is charged with finding the best possible interpretation of the data that he can and then justifying his interpretation with evidence that goes beyond the factor analytic techniques used to obtain that solution. Application of a mathematical algorithm is more objective to be sure, but it does not alter the onus placed on the investigator to justify by other lines of evidence that he has, in fact, found the best structure for the data. If the mathematical algorithm applied happens to be inappropriate for the data and happens to give nonsense for results, it is small comfort to the investigator to know that the process was untainted by human judgment. It is the fond wish of naive investigators that factor analysis should be an objective machine for grinding out truth untouched by human brains. Such fairy tale devices do not exist in the behavioral sciences, nor indeed in the physical sciences. The reality is that factor analysis is somewhat like a microscope. It can help an intelligent and well-trained investigator see things that he could not see with the naked eye, and perhaps derive scientific conclusions of value as a result. The untrained individual looking through a microscope can see many things, but he may not be able to interpret what he sees correctly. The untrained factor analyst also can get a final rotated factor matrix from the computer center, but he may not be in a very good position to draw appropriate conclusions from what he sees. Just as we would not throw out or blame the microscope because an untrained individual uses it improperly, we should not blame the tool itself when factor analysis is applied improperly.

Orthogonal versus oblique axes. The decision to use orthogonal or oblique rotated axes should be a conscious one by the investigator for good cause, not based on just what happens to be available at the computer center. Many investigators give no thought to determining whether they should have an oblique or orthogonal solution and if oblique, how oblique. Conformity to simple structure (more variables with low loadings) can be improved more and more as axes are allowed to become more and more oblique. Some ana-

lytic procedures require the specification of a constant that will put more or less of a brake on this tendency toward greater obliqueness. Others require the specification of a maximum permissible correlation between oblique factors. To avoid inappropriate degrees of obliqueness in the solution, whatever rotational method is used, the investigator should have some idea of what correlations between his factors are reasonable. The actual angles between factors in his oblique solution should be examined with this in mind. If the oblique solution rendered by an analytic computer method yields factor correlations that cannot be justified as reasonable, the investigator should be prepared to modify the solution.

Rotating different numbers of factors. The number of factors rotated in a solution can have a profound effect on the results, especially if a computerized mathematical algorithm is applied. A common error is to extract too many factors and then rotate them all by varimax or some other procedure that seeks something approximating a simple structure type of solution. The varimax algorithm will build up minor factors where possible at the expense of major factors. Especially where the eigenvalue-one procedure is used and too many factors are rotated, the varimax method may produce one or more factors with high loadings for one and only one variable. With a different kind of rotation procedure, this variable might have an important loading on one of the major factors but not when the varimax procedure was used with too many factors being rotated. The presence of a rotated factor with one large loading, say .6 or more, and no other loading above .35, is almost a certain sign of a distorted factor solution when common factor variance is being analyzed.

Skillful hand rotations can avoid the problems associated with rotating too many factors. The extra small factors are simply not allowed to distort the proper appearance of the major factors. It is analytic rotation of these extra factors by mathematical algorithms that is apt to cause a problem. One way of dealing with this problem is to rotate several numbers of factors in the region of uncertainty by the mathematical algorithm

in question and then compare the solutions to see which can be justified best as a proper interpretation of the data. I have developed a procedure called the "tandem criteria" method of rotation (Comrey, 1967) that starts out by rotating more than enough factors. Variance is shunted from the major factors toward the smaller factors, but this process is restrained by the correlations that exist among the variables. Correlated variables are retained on the same factors. After this process, factors that are still too small are dropped. Retained factors are rotated by a different algorithm to provide a more simple structure type of solution. It is often necessary to rotate two or three different numbers of factors in the region of uncertainty before a final decision is made about the "correct" number of factors.

Rotating too few factors, on the other hand, forces the amalgamation of factors into complex composites, obscuring the most useful factor structure. Variance is ordinarily extracted in successively smaller amounts from the first to the last factor, but parts of the variance from several factors appear as each factor is extracted. If only 10 factors are rotated when there are really 12 factors there, most of the variance for the two extra factors will be included in the first 10 unrotated factors. This variance must go somewhere, so it is superimposed on the first 10 factors, distorting their true appearance. Nothing can be done to correct the effects of rotating too few factors, except rerotating with more factors. It is better, therefore, to err on the side of taking out too many factors rather than too few.

One of the main points of this discussion is to suggest that it is often impossible to determine the correct number of factors just by considering the unrotated factors alone. Rotational solutions can often provide important information that will be useful in making this decision. In most empirical analyses, particularly with small samples, there is a good deal of error in the correlations that tends to add surplus variance to the solution. Guertin and Bailey (1970) have pointed out that the larger variability of chance correlations around zero for small samples compared with large samples produces greater commu-

nalities, and in many cases this can mean extra factors. Trying to decide just where the wheat ends and the chaff begins is not easy. The decision should take advantage of every scrap of evidence available to the investigator, including the benefit of comparing solutions with different numbers of rotated factors. This increases the dangers from subjectivity, of course, but for a cautious, scientifically oriented investigator, the benefits outweigh the disadvantages in my opinion.

Confusing factor levels. A persistent problem that plagues many factor analytic investigations is the inadvertent production of low-level factors in the hierarchy of factor generality. A factor of this kind is indicated by the presence on the factor of two or more variables with high loadings that are very similar in character. Thus, systolic and diastolic blood pressure both included in the same analysis will produce such a low-level factor, or at least distort the nature of some factor, depending on the other variables included in the analysis. This is due to the fact that these two variables are highly correlated, measuring very similar phenomena. As another example, consider these two test items (a) I feel blue, and (b) I am depressed. Correlating these items with others and factor analyzing them will produce a low-level factor, with these two items showing high loadings. These two variables are merely alternate forms of the same thing. Any factor analytic solution should be inspected for the presence of such low-level factors. They cannot represent constructs of general interest and scientific utility per se, because these factors can be produced virtually at will. It is only necessary to add another variable to the matrix that is very similar to an existing one, and then a factor will be produced defined by these two variables.

In my opinion, factors are more apt to be useful if they stand at the next level up in the hierarchy of factor generality. The variables with high loadings on the factor should not contain two or more variables that could represent virtual alternate forms of the same thing. Each variable with a high loading on the factor should have a logically distinct and separate identity, measuring something that is not the same as what is being measured by

any other variable on the factor. The high-loading variables defining the factor should be correlated but not alternate forms of each other. In my experience, it is not possible to keep adding factors of this kind in a given domain. One very quickly comes to the end of the line. There is, on the other hand, no end to the number of low-level factors that can be generated. This fact alone favors second-level factors versus first-level factors. At the other extreme, also to be avoided, are factors that are too high in the hierarchy. Factors produced by correlations among highly complex variables, such as several tests of intelligence, are too broad to have much utility. When several second-level factors are found to be persistently intercorrelated, however, a useful third-level construct may be indicated. This is the case with general intelligence, a third-level construct that is generated by the intercorrelations that exist among lower level factors of cognitive performance. Identification of such useful higher order constructs takes place best through the identification of second-level factors that are correlated, not by a direct assault using complex variables in the factor analysis.

Locating a general factor. Occasions arise when an investigator hopes to demonstrate the existence of a general factor running through the variables that he is investigating. One of the common errors in this instance is to take the first extracted factor and treat it as though it were a general factor. This procedure is unsatisfactory, because the first factor vector can easily contain major loadings for entirely unrelated variables. If the factor is to be a general factor, the variables relating to it must be correlated with each other, except in rare special cases involving certain kinds of complex variables. The investigator should make sure that the variables loading on his putative general factor are indeed correlated to a satisfactory degree before he leaps to the conclusion that he does in fact have a general factor. On the other hand, if rotations of several factors are carried out by varimax, for example, or any other method seeking simple structure, the tendency will be to disperse the variance as much as possible, thereby reducing the prominence of any general factor that might be present. It is

desirable to use a method that will permit a general factor to appear if in fact the data warrant it without forcing it on the data. The Criterion I rotational method of the tandem criteria (Comrey, 1967, 1973) is one such method.

Interpretation of Results

The usual procedure in interpreting factor results is to inspect the variables that have high loadings on the factor, look for what they have in common, and then name the factor in accordance with the common elements. Up to this point, the activity is little more than factor naming, and if nothing beyond this is done, the value of the analysis may be rather limited. When a name is given to a factor, a hypothesis has been formulated. Untested hypotheses usually have limited value until something has been done to test them. Ideally, as has been mentioned earlier, the investigator will make plans to carry out additional analyses in which he adds new variables that should have major loadings on certain specified factors and low loadings on other factors if his hypotheses are correct. He will perhaps revise other variables in ways that predict certain outcomes if his factor interpretations are correct. These predictions will be tested by further investigations. Experiments may be carried out, with predictions being made as to the outcome, in which attempts are made to alter scores on one factor but not another. Results of the experiment will confirm or disconfirm the hypothesized factor meanings. In other cases, predictions may be made about how scores for a certain factor will correlate with other variables outside the matrix. When the investigator carries out one analysis and does not follow up after the factor naming to test the accuracy of his factor interpretations, he must recognize that much remains to be done before his interpretation can be regarded as proved.

Writing Up Results

One of the most commonly violated rules of scientific reporting in factor analytic studies is that the writer fails to give enough information to permit another investigator to

repeat his work. There should be sufficient information given about the variables studied so that someone else can also construct or obtain comparable measures if he so desires. The correlational matrix itself should be made available to the reader so that he can evaluate the adequacy of the solution reported or carry out his own preferred type of analysis on the data. Future developments may also provide more powerful methods of analysis that can be applied to the same matrix, provided that the matrix is made available. Many factor analyses appear in manuscripts submitted for publication that fail to contain this information, making it exceedingly difficult to evaluate the work. True, these matrices often cannot be published in the article itself, but at least they can be made available through auxiliary publication outlets and certainly should be available to journal editors.

Beyond this minimum, the investigator should preferably do much more and often fails to do so. He should report enough about his sample so that its impact on the results can be assessed. He should tell what method of carrying out the factor extractions he used, what he did about the communalities and why, and how he determined the number of factors extracted and rotated. He should also make available the unrotated factor matrix, using auxiliary publication outlets.

The method of carrying out the factor rotations should be explained and the reasons given why this is an appropriate method for the data. Some information should be given about why an orthogonal or an oblique solution was chosen. Discussion of the rotational solution with respect to the problems of determining the correct number of factors should show that the investigator at least considered alternate possibilities. The rotated factor matrix should also be made available. If there is an oblique solution, the structure matrix, the pattern matrix, and also the matrix of correlations between factors should be made available. Again, auxiliary publication outlets should be used for these matrices, but the journal editors should have access to these materials at the time of manuscript review.

Sources of Help

In an article such as this, it is possible to point out briefly some common trouble spots in factor analytic investigation and reporting, but it is obviously not possible to say all that needs to be said nor to give adequate advice on how to avoid all possible pitfalls. Several good textbooks are available to help the investigator, each with its own strengths, weaknesses, and special emphasis. A few of the more recent books are mentioned below with brief annotations:

Comrey (1973) assumes a knowledge of beginning statistics and high school algebra and gives elementary treatment of the mathematical background of factor analysis, but the major emphasis is on practical applications. Computer programs are made available.

Gorsuch (1974) contains a balanced approach between theory and applications with a level of difficulty greater than Guertin and Bailey (1970) but less than Harman (1976), Horst (1965), and Mulaik (1972). It is a good introduction to the more difficult books.

Guertin and Bailey (1970) is essentially nonmathematical in its presentation and hence tends to be a "how to" cookbook; despite its weakness on theory, the book contains much useful information and results of many experiments with different factor methods.

Harman (1976), published posthumously, is the latest edition of Harman's widely used text and is an excellent source for the mathematical methods and theory of factor analysis. It is difficult reading for the person who is poorly trained in mathematics, however, and it does not emphasize the practical problems in applying factor analysis.

Horst (1965) is an encyclopedia of information about theory, methods, and techniques in factor analysis. Unfortunately, Horst's notation makes the book very difficult to read for most behavioral scientists.

Mulaik (1972) is a thorough mathematical treatment of factor analytic techniques. The major emphasis is on mathematical theory rather than applications. Unless the reader is fairly sophisticated mathematically, he should probably start with some other book.

Rummel (1970) is a good introduction. It emphasizes applications more than theory and

is similar to the Comrey (1973) and Gorsuch (1974) texts in level of difficulty and mathematical preparation required.

Experimental Methods and Outcome Evaluation

Michael J. Mahoney
Pennsylvania State University

Within the constraints imposed by philosophy of science and the limitations of scientific methodology, experiments are basically attempts to identify causes and to evaluate their effects. All experiments involve a comparison of dependent variable values in the presence of different values of another variable. This comparison is usually accomplished by one of two basic experimental strategies: (a) within-subject designs and (b) between-subject designs. The 12 most common designs are outlined and discussed in the present article. Much of the discussion focuses on the importance of internal, external, and theoretical validity in experimentation and data interpretation. To illustrate the most common threats to these three forms of validity, various components in a hypothetical experimental manuscript are discussed. This discussion is followed by an acknowledgment of the continuum of fallibility along which all experiments fall. It is argued that in the final analysis, our goals should be to strive toward conducting the least fallible inquiries, to cautiously interpret our experiments in accord with their logical warrant, and to guard against the paralysis of complacency regarding the adequacy of current research methods.

The methodologist is often stereotyped as a person who is quite willing to offer criticism but who is generally less adventurous when it comes to the actual execution of research. Although armchair quarterbacking is a common diversion among scientists, the bulk of our strategic insights seems to follow rather than precede the busy work of experimentation. Besides illustrating the old maxim that hindsight is more plentiful than foresight, our post hoc criticisms also seem to exhibit another common theme—namely, that we tend to be more critical of other people's research than of our own. It is, therefore, with some reservations that I comment on experimental problems in clinical psychology. I do not presume that my own research has been methodologically flawless, nor do I harbor many illusions about the limitations of science. The perfect experiment has yet to be designed and is, in some sense, inconceivable (Weimer, 1977). Even if it were conceivable, however,

it is a safe bet that it would be impossible to execute. Among other things, the human element in science makes it an inevitably fallible endeavor (Mahoney, 1976; Mitroff, 1974). Let us therefore dismiss the notion of an ideal experiment and instead devote our attention to the continuum of fallible effort along which all experiments must fall. In this regard, our past mistakes and costly hind-sights may well serve to refine our continuing attempts to improve the field of clinical psychology.

As clinical researchers, it is our goal to harness the powers of science in a manner that will help us refine human services—particularly psychotherapy and counseling. This might sound like a rather straightforward undertaking in that it would seem to require only a knowledge of scientific methods and the opportunity to apply them to problems of human distress. As it turns out, however, few undertakings are quite as ambitious as the scientific study of therapeutic interaction. This may be due in part to our poor understanding of the nature of science (Lakatos & Musgrave, 1970; Weimer, 1977). At this point in time, for example, no acceptable cri-

Requests for reprints should be sent to Michael J. Mahoney, Department of Psychology, 417 Bruce V. Moore Building, Pennsylvania State University, University Park, Pennsylvania 16802.

erion has been established for the demarcation of science from nonscience. We must therefore proceed, if at all, with a humility about our understanding of what it is that constitutes "good scientific research" and show considerable tolerance for statements that convey relativity and tentativeness. Today's science may well be tomorrow's alchemy, and it is imperative that this contextual feature be appreciated. With these apologetics in mind, we can now proceed to a discussion of contemporary issues that bear on the evaluation of research.

Fundamentals of Experimental Method

In at least one sense, science is a search for order—an attempt to discern, describe, and apply systematic covariations between events. Order is a prerequisite for prediction, and accurate prediction is a first step toward control. This is why the assumption of determinism cuts so deeply into the core of scientific methodology (Hook, 1958). Although systematic covariation is a prerequisite for accurate prediction, however, it is hardly sufficient for the inference of a cause-effect relationship. This, of course, relates to the oft-quoted difference between correlation and causation, or what David Hume regarded as the distinction between *sequence* and *consequence*. Because covariation, no matter how systematic, can never demonstrate causation, correlational inquiries (or "associative" studies) are often considered nonexperimental in nature. This is true, of course, if one defines an experiment as requiring an active manipulation of one or more variables. It should be kept in mind, however, that associative inquiries are hardly uninformative. Although they can never conclusively demonstrate causality, this is also true of the best conceived experiment. The difference between the two is not as dichotomous as some might expect, with both types of inquiry varying in the relative strength of the conclusions they warrant. Moreover, correlational studies *can* disconfirm some hypothesized relationships, and in this sense they are capable of corroborating a hypothesis. There is a tremendous difference between corroboration and confirmation, however, which we shall explore in a

moment. For the time being it is worth noting that such sciences as astronomy and meteorology are almost exclusively correlational, yet their progress is unmistakable. Having made this brief defense of associative inquiry, I shall hereafter restrict my comments to the topic at hand—namely, problems in *experimental* research as it has been traditionally conceived.

There are, of course, substantial parallels and yet important differences among the concepts of prediction, causation, and explanation. Since the technical aspects of these terms have consumed entire volumes, only the most superficial rendering could be offered here. I shall therefore defer to Weimer's (1977) more extensive discussions, which bear direct and significant implications for the conduct of research. In lieu of a more technical digression, suffice it to say that contemporary scientists often require the following in their evaluation of a causal relationship:

1. relative temporal contiguity (togetherness in time);
2. priority (the cause must precede the effect);
3. noncontradiction (no observed instances of the cause without the effect);
4. factor isolation (the elimination or control of all possible influences other than the one being examined); and
5. replicability (the capacity to replicate the alleged relationship).

The logical validity of these criteria will not be examined here, but this should not be interpreted as complacency regarding our understanding of the concept of causation.

Scientific experiments are basically attempts to identify causes and to evaluate their effects. This is usually accomplished by making systematic changes in one or more factors (the "independent variables") and looking for any covarying changes in other factors (the "dependent variables"). The division of factors into independent and dependent categories is often arbitrary, and in some inquiries auxiliary variables are measured (e.g., to evaluate whether they can help predict the prerequisites or range for a cause-effect influence). Common to all experiments, however, is the act of comparison. *All experiments involve a comparison of dependent variable*

values in the presence of different values of another variable. In extreme form, the manipulated (independent) variable may take on dichotomous values (e.g., present vs. absent). The basic question, of course, is whether different values of the dependent variable(s) are associated with different values of the independent variable(s). This comparison is usually accomplished by one of two basic experimental strategies: (a) within-subject designs and (b) between-subject designs.

Within- and Between-Subjects Designs

As the term implies, within-subject designs are ones in which the comparison is made *within* the same subjects across time. That is, the dependent variable is measured at least after the introduction of the independent variable, and perhaps before or during experimental intervention. This may be done with a small number of individuals, in which case it is called "single subject" or " $N = 1$ " research. The merits and shortcomings of single-subject research have received considerable attention (cf. Greenwald, 1976; Hersen & Barlow, 1976; Kazdin, 1973; Sidman, 1960; Thoresen, in press). Within-subject comparisons can also be performed en masse on a single group of individuals, however, so that the within-subject design is not necessarily restricted to studies involving very few subjects.

Between-subjects designs also attempt to compare values of the dependent variable(s) in the presence of different values of the independent variable(s). In these experiments, however, the primary strategy is to look at differences *between* persons who, for example, have and have not been exposed to the independent variable(s). Historically, most between-subjects designs have involved comparisons between groups rather than individual subjects, and thus the between-subjects design is often equated with "group research." It should be kept in mind, however, that both involve the aforementioned comparison. There are many varieties of both within-subject and between-subjects designs. Many of the former are outlined in Hersen and Barlow (1976), and between-subjects designs are extensively described in Campbell and Stanley (1963) and Paul (1969). The 12 most com-

mon designs will be outlined later, but we should first discuss three types of experimental validity.

Validity: Internal, External, and Theoretical

Few terms in scientific research have been applied as widely as the word *validity*, which, to make matters worse, takes on different meanings in its various uses. Without listing its numerous other uses and varieties, the term *validity* will here refer to "logical warrant" or the extent to which a statement or procedure is logically consistent with the experimental intent. Borrowing from Campbell and Stanley (1963), *internal validity* refers to the extent to which a given set of procedures allows one to draw valid conclusions about what actually happened in an experiment. When an experiment exhibits maximal internal validity, one has relatively strong logical warrant for deciding (a) whether an "effect" occurred and (b) whether that effect can be attributed to the independent variable(s) in question. *External validity*, on the other hand, refers to the extent to which a set of experimental procedures allows one to draw valid generalizations to other subjects or situations. A cause-effect relationship that has only been observed in a very small or unrepresentative sample of subjects would be said to have little external validity in the sense that its generalizability is severely restricted. To exhibit external validity, an experiment must first demonstrate internal validity. One would hardly want to generalize an observed relationship if the validity of that relationship were itself in question. Internal validity is therefore a prerequisite for external validity.

A third—and often overlooked—form of validity is *theoretical validity*, which refers to the logical bearing of an experiment on some hypothesis or theory. Although there are occasional exceptions in the early exploratory stages of a research program, the vast majority of experiments are conducted to test a hypothesis or a theoretical prediction. No single experiment is ever crucial in such evaluations (Lakatos, 1970), but it is still important that the experimental procedures be clearly relevant to the hypothesis in question. In fact, many scientific controversies focus on what

constitute an adequate experimental test of some hypothesis (Kuhn, 1962). Moreover, researchers may argue about which hypothesis is most relevant to the current state of the art. In their analysis of this issue, Vitroff and Featheringham (1974) expand on the popular notions of Type I and Type II errors and talk about a Type III error—namely, the probability of having conducted the wrong experiment. Ideally, then, an investigator attempts to

1. design an experiment whose outcome will have clear logical bearing on some focal hypothesis (theoretical validity);
2. execute that experiment in a manner that will maximize his or her logical warrant for concluding whether an effect occurred and to what factors the effect could be attributed;

3. use procedures that will maximize the generalizability and replicability of any observed relationship.

Campbell and Stanley (1963) and Kazdin (1973) discussed some of the factors that pose potential threats to these experimental ideals. The risk of exclusion and oversimplification, the 10 most common culprits in experimental inadequacy might be considered the following:

1. selection of a theoretically irrelevant hypothesis or issue;
2. use of a subject sample that is very small or unrepresentative of the population to which generalizations are to be drawn;
3. in the case of between-subjects designs, the absence of random assignment to the various experimental conditions;
4. poor specification of the independent variable(s);
5. inadequate standardization, assessment, or description of how the independent variable was implemented;
6. inadequate control for factors other than those of immediate experimental interest;
7. inadequate replication of the cause-effect relationship (either within or between subjects);
8. poor choice, specification, or assessment of all relevant dependent variables;
9. inadequate data presentation; and
10. conclusions or interpretations that are

not logically warranted by the experimental procedures.

Since these experimental flaws are most commonly cited post hoc—as in a journal referee's comments—it might be worthwhile to briefly expand on each in the context of a hypothetical manuscript.

Anatomy of an Experimental Manuscript

For purposes of illustration, let us assume that we are evaluating a hypothetical study on the topic of whether extrinsic rewards can actually undermine a person's interest in some activity. This issue has recently become a very controversial one (cf. Deci, 1971, 1972; Lepper, Greene, & Nisbett, 1973; Levine & Fasnacht, 1974). Some attribution theorists have argued that extrinsic rewards (such as tokens) may cause a person to devalue the rewarded activity and to "infer that his actions were basically motivated by the external contingencies of the situation, rather than by any intrinsic interest in the activity itself" (Lepper et al., 1973, p. 130). Others have defended the use of extrinsic rewards in certain situations to motivate performance.

Introduction

In the introductory section of our hypothetical manuscript, it would be easy to defend the timely relevance of this issue. On the other hand, an introduction usually includes a specification of experimental hypotheses and a preface to the methods used. It is here that theoretical validity is often threatened in that a hypothesis may be oversimplified or illegitimately inferred from a parent theory. For example, in our illustration, it is hardly the case that attribution theory predicts a decline in intrinsic interest every time extrinsic reinforcement is used. Among other things, the individual's perception of the reinforcer may moderate this alleged effect (cf. Steiner, 1970). It would therefore be misleading to state the experimental hypothesis (implicitly or explicitly) as "extrinsic rewards (always) lead to a decrease in intrinsic interest."

Method

As one moves into the Method section of the article, the number of potential threats

to validity increases substantially. For example, who are the subjects? There are practical constraints on the research populations to which most of us have access, and this is understandable. We must bear in mind, however, that these constraints will take their toll in limiting the generalizability of our findings. If we study the behavior of a small group of preschoolers in a progressive academic community, our warrant for generalizations is accordingly handicapped. In a technical sense, of course, it is impossible to experiment with a "universally representative sample." We cannot hope to include a wide enough range of subjects to allow us to say that they were representative of *all* persons in *all* ways. For practical purposes one must often choose beforehand which factors are most relevant to the generalizability of our findings. Subsequent replications and extensions of a study may help clarify its external validity. The use of laboratory analogues and "nonclinical" populations also bears on external validity, and current writers appear to be divided on the conceptualization and merits of such research (cf. Bandura, 1978; Bernstein & Paul, 1971; Kazdin & Rogers, 1978).

In addition to the importance of a representative sample, most methodologists encourage the use of "random assignment" in between-subjects research. Essentially, this is intended to remove (or at least minimize) biases that might be present if one were to use a nonrandom method of deciding which subjects will experience which experimental manipulation. In our hypothetical study on intrinsic interest, for example, one might be biased in assigning children to experimental versus control groups. If the brighter children were overrepresented in one of these groups, this might constitute a threat to both internal and external validity. By using a random assignment procedure, it is hoped that auxiliary variables will be distributed evenly across the various experimental groups. With an infinitely large sample, this would, in fact, occur, but true random distributions on *all* variables are impossible when one is working with a finite sample. Once again, we face the reality that our methodological ideals can be only crudely approximated in actual practice. This is particularly apparent when one is

working with preformed groups (e.g., classrooms), which must be dealt with *en masse*. These groups often present practical impossibilities for individual random assignment, and the conclusions drawn from such endeavors must be appropriately cautious. Alternatives to random assignment include matching (yoking) and blocking (tiering), but these introduce complexities in data interpretation (Feldt, 1958).

One of the most common (and frustrating) shortcomings of an experimental article is the failure to clearly specify the independent variable(s). It would not be informative, for example, to report that "subjects were reinforced for playing with jigsaw puzzles." A colleague who might want to replicate one's efforts would be hard pressed to determine what actually took place on the basis of such a cursory and superficial description of procedure. What constituted the reinforcer? Who administered it? How was it presented? Was the experimenter always the same person? Good operational specifications of procedure are essential not only to facilitate replication but also to clearly communicate what it was that was manipulated. It is difficult to interpret an experimental outcome if one is unclear about the independent variable.

Related to this need for clear operational descriptions of procedure is the importance of assessing the presence and variability of the independent variable(s). This is particularly apparent when the presence of the independent variable is not totally in the hands of the experimenter. In our hypothetical manuscript, for example, there are at least two possible implications of the simple procedural statement that "subjects were reinforced"—namely: (a) Subjects were presented with positive stimuli, and (b) the reinforcement value of these stimuli was reflected by increases in the target behavior. This second meaning derives from the common (if problematic) definition of reinforcement as a procedure that increases the future likelihood of specified performances. In our hypothetical study, suppose the experimenters "reinforced" children with candy. One might expect little controversy over whether the children had "really" been treated in a manner relevant to the experimental hypothesis. In point of

act, however, candy might have been a relatively unrewarding stimulus under some circumstances (e.g., right after a prior classroom snack or lunch). To insure greater relevance to the hypothesis in question, one would want to (a) investigate the children's reinforcement history and/or involve them in the selection of reinforcing stimuli; (b) operationally specify how, when, and by whom these were presented; and (c) assess their effects by evaluating associated performance changes.

This digression on the assessment of independent variables is an important one and should be illustrated in a wide range of situations. Its moral would seem to be *don't take the independent variable for granted*. As a researcher, you may have gone to great pains to train therapists and/or otherwise prepare for the administration of an independent variable. These efforts may facilitate—but they cannot insure—the standard and consistent implementation of that variable in the experiment proper. Logically, it is always safest to double check and monitor the actual carrying out of experimental procedures. As the annals of history will attest, too many conclusions have been drawn on the presumed infallibility of a researcher (Barber, 1976; Mahoney, 1976). One need not lack integrity or competence to exhibit variability in the administration of even the most simple experiment, and these variations may figure prominently on the interpretation of one's data.

Inadequate specification and assessment of independent variables are certainly a common concern of journal reviewers, but they almost pale in comparison to the frequency with which a manuscript is criticized for lacking appropriate control conditions. Just as it is impossible to achieve true random assignment, it is theoretically impossible to control for all possible influences other than the variables of interest. In our hypothetical study, for example, one might include a control group that was rewarded noncontingently as an attempt to control for such factors as mood, the subjects' perception of the experimenter, and so on. Such a group might be informative, but it would hardly be sufficient in isolating potential influences. Given the infinite array of potential variables in most experiments, one

must usually decide to control for the "most likely" influences extraneous to the experimental variable(s). This obviously shades the decision of which variables are most likely to need controlling. The researcher is aided (or perhaps abetted) here by some historical consensus on the most likely "artifacts" in experimental research. At the risk of oversimplification, they are: (a) maturation (cf. Campbell & Stanley, 1963), (b) subject expectancy (cf. Wilkins, 1973), (c) experimenter bias (cf. Barber, 1976; Orne, 1962; Rosenthal, 1966; Rosenthal & Rosnow, 1969), (d) assessment (i.e., the effects of measurement alone), (e) participation (i.e., the effects of involvement in an experiment), and (f) differential attrition (i.e., selective loss of subjects from some experimental conditions).

The history of methodological refinements in the behavioral sciences is basically a history of attempts to control for such variables as these. The 12 most common experimental designs are illustrated in Table 1, which draws heavily on the early conceptualization of Campbell and Stanley (1963). In the table, a 0 refers to an observation or assessment and an X refers to some form of intervention or treatment. Reflecting some of my own biases, the designs outlined in Table 1 are listed in a crude progression of validity (i.e., with the later designs exhibiting greater internal and external validity than the earlier ones). Unfortunately, Designs 10, 11, and 12—which promise the strongest logical warrant—are among the least popular in the field.

It is also noteworthy that two of the most crucial threats to internal validity are among the most neglected in behavioral science research, that is, subject expectancies and experimenter bias. Literature ranging from the "placebo effect" to psychotherapy outcome documents the potential influence of subject expectancies in an experiment (cf. Badia, Haber, & Runyon, 1970; Kazdin & Wilcoxon, 1976; Shapiro, 1971). If a person *participates* in an experiment, his or her behavior is likely to be different than that of a nonparticipating control subject. One might say "of course—that just shows that an effect has occurred." Unfortunately, many studies suggest that simple participation in *any* experience that is presented as "treatment" may produce thera-

Table 1
The 12 Most Common Experimental Designs

Design	Symbol	Description	Comments
		Within subject	
1. Posttest only	X0	A person or group experiences a manipulation (X) (e.g., therapy), and the dependent variable is then measured (0).	Extremely weak and uninformative design; no strong conclusions can be drawn.
2. Pretest-posttest	0X0	The dependent variable is measured (0) before and after the experimental manipulation (X).	Weak design; it may be concluded that there was (or was not) a change in the dependent variable, but one cannot determine whether this change would have occurred anyway (without the experimental manipulation).
3. Reversal	0X0X0	Two separate manipulations of the independent variable are each preceded and followed by measurement of the dependent variable.	More adequate design in that it can replicate the observed effect of an experimental manipulation; conclusions are limited to the subject or group in question, however, and this design does not rule out the possible influence of factors other than the independent variable; reversal may pose practical and ethical problems in some situations.
4. Equivalent time samples	0X0X0X0X0X	An extension of the reversal design in which an independent variable is sequentially presented and removed (or otherwise manipulated) with alternating measurements of the dependent variable.	Moderately adequate design in the sense of multiple replication and possible control of some time-related factors; limitations include the possibility that the effects of a manipulation may change due to its repeated presentation and withdrawal.
5. Multiple baseline	0X000 00X00 000X0	The timing of an experimental manipulation is systematically varied across different behaviors or situations.	Moderately adequate design in that it includes replication and partial control of time-related factors; limitations vary with the specific procedures.
6. Time series	000X000	The stability of a dependent variable is measured; deviations from that stability after an experimental manipulation are used to infer causal relationship.	Somewhat controversial in terms of adequacy; limitations include failure to rule out factors that changed simultaneously with the experimental manipulation and failure to replicate.
7. Changing criterion	0X ₁ 0X ₂ 0X ₃	Similar in some respects to equivalent time samples design, except that the value of the independent variable is systematically altered; if changes in the dependent variable reliably covary with these manipulations, a causal relationship is inferred.	Moderately adequate design that shares many of the strengths and weaknesses of the equivalent time samples design; in addition, this may be problematic with some patterns of criterion change.

Table 1 (continued)

Design	Symbol	Description	Comments
		Between subject	
8. Multiple baseline	0X000 00X00 000X0	The timing of an experimental manipulation is systematically varied across persons or groups.	See multiple baseline design within subjects (5).
9. Control group	0X0 0 0	Subjects are randomly assigned to an experimental or control condition (usually groups); the independent variable is manipulated only in the experimental condition, but the dependent variable is measured (pre and post) in both.	Generally adequate design whose limitations include failure to evaluate the effects of being observed or participation in <i>any</i> experiment.
10. Solomon four group	0X0 0 0 X0 0	Subjects are randomly assigned to four conditions (usually groups), two of which will receive the experimental manipulation—one of these is tested (i.e., the dependent variable is measured) before and after the manipulation; the other is tested only after; in the two control conditions, one is tested pre and post, the other only post.	Very adequate design in that it controls for the effects of testing; limitations include failure to evaluate the contribution of participating in <i>any</i> experiment.
11. Attention and control group	0X0 0 0 X0 0 0Y0 Y0	Subjects are randomly assigned to six conditions (usually groups), four of which are identical to those in the Solomon design; the two remaining receive some form of contact or attention designed to control for simple participation in an experiment.	Very adequate design; major limitation is failure to control for subject expectancies.
12. Placebo and control group	0X0 0 0 X0 0 0Z0 Z0	Identical to Design 11, except that the two added conditions receive an experimental manipulation that has an equal degree of credibility or probable effects as the true experimental manipulation; the placebo's probable effects are evaluated by subjects.	Very adequate design; the placebo condition simultaneously controls for participation and expectancy.

peutic changes in some individuals (Shapiro, 1971). This is particularly the case when (a) the subject believes that he or she is receiving

a treatment (or experimental) variable and (b) the subject harbors positive expectancies about the probable effects of the variable in

question. Humans tend to be active generators of hypotheses, and they may often try to guess an experimenter's hypotheses as well as their group assignment. They are then more likely to be influenced by their own expectancies and what they perceive as the demands of the situation (cf. Orne, 1962).

Particularly important in research on the outcome of a psychological treatment are controls for participation and subject expectancy. This is most efficiently performed by the placebo and control group design (Design 12 in Table 1). It should be noted, however, that a "placebo" (i.e., inert) treatment only controls for subject expectancies to the extent that it is perceived (by the subject) as being equally credible and powerful as the experimental treatment(s). One cannot presume to determine these factors without involving the subjects themselves. That is, one cannot dictate the credibility of a placebo or presume that subjects will expect to benefit as much from it as from one's experimental treatment. These are empirical issues that may require pilot studies and that certainly merit assessment in each application of the placebo.

None of the designs outlined in Table 1 specify controls for experimenter bias—the artifacts that may be introduced in an experiment (consciously or otherwise) by the investigator. Although experimenter effects are seldom granted much concern in clinical research, the available evidence suggests that this complacency may be quite costly (cf. Barber, 1976; Mahoney, 1976; Rosenthal, 1966; Rosenthal & Rosnow, 1969). It is not an insult to the integrity or competency of a researcher to acknowledge that he or she may exhibit subtly human patterns of fallibility that may threaten the internal validity of an experiment. In some instances, the experimenter may bias things against his or her hypothesis, but more often than not the prejudice seems to favor rather than challenge the hypothesis in question. It is partly for this reason that *independent* replication is so important. On the other hand, we now know that scientists can independently replicate a spurious phenomenon dozens of times if they share the same expectancies (cf. Mahoney, 1976). For this reason, it is important to endeavor toward maximizing the objectivity of

the investigator(s) by such means as using experimenters who are "blind" (uninformed) about the hypotheses and/or subject conditions. Multiple raters or persons with contrary biases may also help to assess (and hopefully minimize) experimenter bias. No single method is ever completely effective in eliminating this factor, and an inability to control for experimenter bias does not mean that a study should not be conducted. It does, however, restrict one's logical warrant for confident data interpretations.

Results

The results section of a manuscript may play an important role in its fate—particularly if the results run contrary to popular assumptions or the biases of the reviewers (Mahoney, 1977). The psychology of science is not, however, our current concern. More relevant are the factors that bear on manuscript evaluation and become most salient in the Results section. These include (a) choice of dependent variables; (b) specification and assessment of dependent variables; (c) data presentation; (d) descriptive statistics; (e) inferential statistics; and (f) in treatment studies, maintenance and/or generalization of therapeutic effects.

In most cases, the choice of dependent variables may seem straightforward and uncontroversial. When concern is expressed about the outcome measures in an experiment, it most often bears on (a) the relevance of the variable to the hypothesis, (b) the failure to assess other relevant variable(s), and (c) the assessment methods used. In our hypothetical manuscript on intrinsic interest, for example, subjects' actual performance rates might appear to be a straightforward outcome measure. If the task involved jigsaw puzzles, however, one must decide whether to assess time spent in the activity, number of units completed, the "vigor" of responding, and so on. Likewise, a more comprehensive outcome assessment might be facilitated by asking subjects to rate their interest in the experimental activity.

Assessment methods constitute an ambitious topic in and of themselves, and they cannot be adequately examined here. At the risk of seeming perfunctory, I shall offer a handful of

suggestions in this regard. First, one is well advised to use *multimodal assessment*, that is, a variety of dependent variables and assessment methods that may lend consensual confidence to one's observations. Direct observations of behavior, physiological measures, subjective self-reports, unobtrusive measures, and standardized psychometric instruments may each contribute to one's confidence regarding the nature and magnitude of an experimental effect. Wherever possible, the assessment instruments should be chosen from among those that are professionally recognized as having demonstrated acceptable reliability (consistency) and relevance to the outcome in question. When direct behavioral observations are used, response categories should be clearly defined and independent interrater reliabilities should be reported. More extensive discussion of these points and some of the more popular instruments are available elsewhere (cf. Cone & Hawkins, 1977; Cronbach, 1970; Hersen & Bellack, 1976; Meehl, 1973; Mischel, 1968; Webb, Campbell, Schwartz & Sechrest, 1966).

Data presentation is another topic that could consume a volume in and of itself. Although it is usually impossible to publish one's raw data in their entirety, it is important that they be summarized in an objective and communicative fashion. It is also a scientist's obligation to make his or her raw data available to colleagues (cf. Wolin, 1962). The goal in data presentation is to be concise without sacrificing content. This can usually be accomplished by a judicious construction of figures and tables. The tables or text should include relevant descriptive statistics that report more than one measure of central tendency and indicate the range and variance of the data in question.

Use of "appropriate" inferential statistics is another controversial point, and many manuscripts encounter problems in this area. Some of the most common concerns here include

1. appropriate choice of a statistical test (e.g., parametric or nonparametric, variance or covariance analysis, etc.);
2. application of the test to the appropriate dependent variables (e.g., posttest scores versus change scores);
3. protection against probability pyramiding (Neher, 1967) through use of conservative

significance levels or appropriate post hoc comparisons;

4. failure to attend to issues of power in selecting sample size and significance level;

5. failure to consider the possible role of statistical regression in the obtained results; and

6. failure to distinguish between statistical significance and clinical significance.

The amount of emphasis placed on statistical inference is substantial, and there is likely to be vigorous debate regarding Weimer's (1977) recent demonstration that all contemporary inferential statistics are illogically founded. The logic of his proof is straightforward and may raise the ire of many a science apprentice who has been forced to develop traditional statistical proficiencies (Mahoney, 1976). I shall avoid the temptation to expand on that proof and instead suggest that we might do well to imitate the physical sciences in their rejection of null hypothesis testing as an automatic and rational arbiter of experimental results (cf. Greenwald, 1975; Meehl, 1967). Reports of percentage of outcome variance attributable to the independent variable(s) might offer a more rational and constructive alternative to our present inferential statistics. One should bear in mind, however, that this is still a minority view and that the vast majority of psychologists—and journal referees—hold few things more sacred than significance levels.

In clinical outcome evaluations, the generalization and maintenance of a therapeutic effect often constitute important factors in the professional response to a manuscript. Maintenance is a particularly salient concern, perhaps because it has been such an elusive feature in our efforts to facilitate human adjustment. Short-term therapeutic effects are not difficult to produce in some behavior disorders. Short-term improvements that can be confidently attributed to the treatment in question are much less common; enduring and attributable therapeutic improvements are a rarity indeed. It is, I think, a promising sign that contemporary journals are now demanding more refined methodologies and demonstrations of long-term maintenance.

Discussion

How one's data are interpreted depends, in part, on how they have been analyzed and

whether their implications are obvious. In the case of the latter, one can occasionally find consolation in their having passed the test of "interocular trauma," that is, when the effect or outcome is so salient that it "hits one between the eyes" (Weimer, 1977). In the absence of such a dramatic event, one must draw conclusions about (a) whether an effect was observed (e.g., therapeutic improvement), (b) whether an effect (if present) can be attributed to the independent variables, (c) how the present findings bear on the hypothesis or theory in question, and (d) how widely the present findings can be generalized. These conclusions are obviously related to the issues of internal, external, and theoretical validity.

Most researchers are well versed in the designs that will allow them to confidently assert that an experimental effect was observed (Table 1). There is much more room for interpretive license (and error) when it comes to asserting that the independent variables were responsible for such an effect. It is here that adequate controls and protections of internal validity are most relevant. In our hypothetical study on intrinsic interest, for example, one could conclude very little from a control group design (see Design 9, Table 1) due to the plethora of competing variables (e.g., access to the target task, boredom, etc.) Errors or excessive license in causal attribution are a common concern of journal reviewers, as are overgeneralizations (cf. Maher, 1978). Interestingly, another form of logical error that is seldom noted may be one of the most common, and its effect may be among the more pernicious.

When the experimental data are consistent with one's hypothesis (and the null hypothesis has been rejected if one has been stated), it is very common for the researcher to conclude his or her article with a *confirmation claim*. In its essence, a confirmation claim is an assertion that the truth value of a proposition or hypothesis has been strengthened, proven, or otherwise augmented. This is unfortunate and misleading, because *no empirical hypothesis can ever be confirmed* (Mahoney, 1976; Weimer, 1977). Confirmation refers to a form of logical inference in which a true premise warrants a true conclusion. Consider, for example, the hypothesis that "if theory A

is true, then observation X will occur." Logically, the confirmation of this hypothesis requires that one be told that the premise is true, after which one could rationally infer that the conclusion is also true (i.e., that observation X will, indeed, occur). This is obviously of little use to the scientist, since the truth value of the premise is most often the point at issue. Philosopher Karl Popper has noted this for years, and yet scientists persist in their claims of confirmation (cf. Popper, 1959, 1963, 1972).

When a researcher reports findings that are consistent with his or her hypothesis and then argues that these data "support" the hypothesis, a serious logical error has been committed. Technically, the error is called *affirming the consequent*. It consists of making the illogical inference that a true conclusion implies a true premise. In my earlier illustration (in which theory A predicted observation X), the occurrence of observation X has absolutely no logical bearing on the truth value of the premise (theory A). The observation of not X would, however, bear clear logical implications for the theory. As we all learned in elementary algebra, it is only false conclusions that bear conclusively on a premise (i.e., they can falsify it). This was, in fact, the cornerstone of Popper's philosophy of falsificationism. Counterintuitive as it may seem, negative results and predictive failures have far-reaching logical implications, and positive results (successful predictions) have comparatively little information content. This is, of course, contrary to the popular practice of selectively publishing positive results manuscripts and emphasizing these successes more heavily in literature reviews (Meehl, 1967). The epistemological costs of this practice are themselves quite distressing (cf. Mahoney, 1976; Smart, 1964).

So what does one do with "positive results," that is, an experimental outcome that is consistent with the hypothesis in question? How are these to be interpreted? In a word, cautiously. One can legitimately note their consistency with the hypothesis or state that they *corroborate* the hypothesis. Loosely speaking, corroboration refers to the act of having survived falsification (Popper, 1972). To say that a hypothesis has been "corroborated" is

simply to state that it has been tested and has (tentatively) survived. This is very different, of course, from implying that it has been strengthened. No matter how many times a hypothesis survives falsification, it can never be legitimately said to have been "confirmed" or "supported." As corroborative instances accumulate, most of us experience a *psychological* increase in our confidence regarding the hypothesis in question. This subjective phenomenon should not, however, be confused with the logical warrant of the situation. As much as we scientists may like to view ourselves as rational creatures, there is a clear and significant difference between our rare use of logic and more common use of psycho-logic.

Concluding Remarks

It has not been my intent to overemphasize the shortcomings of science or to criticize our attempts to use experimental methods in the refinement of therapeutic interaction. We must recognize, however, that all of our scientific efforts fall along a continuum of fallibility. There is no investigation that can be *totally* lacking in its potential informativeness, nor will there ever be one that is perfect in its attainment of internal, external, and theoretical validity. Our goals, then, should be to strive toward conducting the least fallible inquiries, to cautiously interpret our experiments in accordance with their logical warrant, and to guard against the paralysis of complacency regarding the adequacy of current research methods. One of the most pervasive aspects of scientific endeavors has been their exploratory character, and we are, I think, well advised to explore refinements in both our methods as well as our technical knowledge. As illustrated in the cases of inferential statistics and confirmation claims, these explorations may require some psychologically unsettling changes—from old "accepted" procedures to newer alternatives. As such, they may require a reappraisal of long-revered assumptions about the best way to do scientific inquiry. In the final analysis, however, the prospect of progress will hopefully overshadow the inconvenience it may demand. We can, after all, hardly expect to "grow" if we are unwilling to change.

Evaluating the Generality of Findings in Analogue Therapy Research

Alan E. Kazdin
Pennsylvania State University

Analogue research in psychotherapy and behavior therapy has proliferated in recent years. The value of analogue research is that it allows analytic and well-controlled research to address questions that often are prohibitive or impractical to evaluate in clinical situations. The major source of controversy about the value of analogue studies is their external validity, that is, the extent to which the results can be generalized to the clinical situation. Much of the controversy stems from conceptualizing therapy investigations discretely as either analogue or clinical research. However, all treatment research is an analogue of the situation to which an investigator wishes to generalize. Thus, the main question is the extent to which an investigation is an analogue of the clinical situation. An investigation can vary from the clinical situation along several dimensions, such as the target problem, the clients studied, the manner of client recruitment, and others. It is often assumed that the greater the similarity of an intervention to the clinical situation, the more likely the findings will be generalizable to the clinical situation. The present article questions this assumption and suggests an empirical method for evaluating the generality of therapy research to the clinical situation.

Investigation of treatment outcome has been and continues to be a major research topic in psychotherapy and behavior therapy (e.g., Bergin, 1971; Eysenck, 1952; Kazdin & Wilson, 1978; Luborsky, Singer, & Luborsky, 1975; Meltzoff & Kornreich, 1970; Paul, 1969; Rachman, 1971; Sloane, Staples, Cristol, Yorkston, & Whipple, 1975). The goals of therapy outcome research usually are to determine the efficacy of a given treatment, to evaluate the relative effectiveness of different

treatments, and to assess the components of treatment that are responsible for change for a particular treatment problem and client population. The most direct means of achieving these goals is to study the therapy techniques and populations of interest directly in a clinical setting. The requirements for conducting clinical research appear relatively straightforward. Clients who seek treatment for a given problem at a treatment facility can be assigned to different treatment or control groups, depending on the research questions and desiderata of the experimental design. Treatment can be administered by trained therapists and evaluated by assessment of therapeutic change on multiple measures of the clients' problems.

This article was written while the author was a Fellow at the Center for Advanced Study in the Behavioral Sciences, Stanford, California. Fellowship support was obtained from the Foundations Fund for Research in Psychiatry, National Institute of Mental Health Grant 1-T32-MH14581 and the Spencer Foundation, which the author gratefully acknowledges.

The author is grateful for the extensive discussions and specific comments on the article provided by W. Stewart Agras, Nathan H. Azrin, Alexander George, Walter Mischel, Stanley Rachman, and G. Terence Wilson, who also were Fellows at the Center for Advanced Study in the Behavioral Sciences.

Although the basic requirements for outcome research might be highlighted in a straightforward fashion, meeting these requirements in practice presents nearly insurmountable obstacles for the researcher. Because of the diverse practical and ethical obstacles of clinical research and the complexity of treatment, a great deal of research has been

conducted in situations analogous to those available in the clinic. Research that evaluates treatment under conditions that only resemble or approximate the clinical situation has been referred to as "analogue research." An analogue study usually focuses on a carefully defined research question under well controlled conditions. The purpose of this investigation is to illuminate a particular process or to study an intervention that may be of importance in actual treatment.

An important issue in the psychotherapy and behavior therapy literature is the extent to which analogue studies contribute to understanding therapeutic processes and outcome in clinical settings. It is generally acknowledged that analogue studies are essential and that they provide an important link in extrapolating from basic laboratory research to therapy. However, even in the most well-designed analogue investigations, there is a lingering concern about the external validity of the results, that is, the generalizability of the findings to the clinical situation.

Whether analogue studies provide a basis for drawing conclusions about the clinical efficacy of a given treatment technique is a matter of dispute. The purpose of the present article is neither to defend nor to criticize the use of analogue research. Indeed, a basic tenet that will be advanced is that experimental treatment research invariably is analogue research. The purpose of the article is threefold. First, treatment research is conceptualized in such a way as to question the utility of the notion of analogue research as a distinct category of therapy studies. Second, dimensions for determining the extent to which a given study is an analogue of clinical treatment are examined. Finally, and most importantly, a way of studying directly the relationship between analogue and treatment studies is suggested. Hopefully viewing the analogue nature of treatment research as a matter of degree and suggesting a method for investigating generality of the findings of treatment research will stimulate an empirical research in questions of external validity.

Utility of Analogue Studies

Conducting therapy research in the clinical setting in which treatment normally is pro-

vided presents several obstacles. The obstacles encompass practical difficulties of undertaking and completing clinical research, as well as ethical considerations that militate against addressing select research questions. The practical problems include diverse aspects of the investigation. Initially, in most treatment studies, it is difficult to obtain a sufficient number of clients with the same or similar problems to meet the requirements for an experiment. Similarity among the clients' problems is required so that measures of their personality or behavior can be compared along the same response dimension (e.g., anxiety, depression, or another dimension) to evaluate the effects of treatment.

Even if clients with similar problems can be included in a given study, often there are constraints in assigning clients to specific forms of treatment. For example, in inpatient treatment, administrative demands sometimes dictate that the more severe patients be given the treatment that is more likely to alter behavior than is some other treatment. In outpatient treatment, clients are not easily assigned to different variations of therapy, because they may seek and express preference for specific treatments. Thus, randomization of assignment, an essential ingredient in most experimentation, may not be feasible.

Another problem in working with clinical populations is that it may be difficult to control or remove the influence of competing factors that can affect therapy results. For example, in outpatient psychotherapy, clients may receive additional experiences (e.g., encounter group or marathon sessions) or counsel (e.g., from a physician) while participating in a given treatment. In inpatient treatment with psychiatric patients, it may be difficult to control ongoing treatments (e.g., drugs) and other factors (e.g., release from the hospital) that can influence treatment or its evaluation.

Aside from obstacles in selecting clients, it is often difficult to obtain therapists who will engage in treatment and meet the demands of research. Initially, there is little incentive for most practicing clinicians to participate in an experiment. Also, it is difficult to recruit clinicians who are homogenous in training and experience. Finally, most experienced therapists are interested in conducting treatment in their own way rather than following the some-

what regimented or standardized procedures that may be needed to evaluate a specific treatment.

Ethical considerations also make clinical investigation of certain questions very difficult (Stuart, 1973). Many important questions about therapy require control groups that withhold specific aspects of treatment that may be crucial for behavior change. To subject clients to "control" conditions that have a low probability of effecting behavior change could violate the professional commitment to treatment. Also, the possible ineffectiveness of a control procedure may lead to relatively high levels of attrition. The problem of assigning clients to control conditions also is evident in cases in which the effects of therapy are evaluated over a protracted period against a group that never receives treatment. A no-treatment or waiting-list control group that may never receive treatment or that receives treatment after a long delay (after they have served their purpose as no-treatment subjects) often is difficult to implement for clients whose problems are in a crisis state when they seek treatment.

Because of the practical and ethical problems highlighted here, therapy research on patient populations with trained therapists in clinical settings is relatively rare. Much of what is known about therapeutic processes and behavior change is learned from analogue studies. The analogue studies are investigations of circumscribed therapeutic processes or problems in a well-controlled laboratory situation. There are many advantages of laboratory investigations of clinical phenomena (Bernstein & Paul, 1971; Levis, 1970; Paul, 1970). As a general statement, laboratory investigations of therapy allow the investigator to control the conditions of experimentation to a much greater extent than do clinical investigations. This careful control allows the investigator to minimize sources of variance that might obscure an effect of treatment in situations in which several parameters are free to vary. Thus, the subjects who receive treatment can be selected because of their similarity in the type of target problem, the severity of the problem, and subject and demographic variables that might contribute to the variability of treatment effects. Aspects of treatment can be carefully controlled in analogue

research that otherwise would vary considerably in treatment. For example, therapists can be selected because of their homogeneity with respect to experience, age, training, and other factors. Also, the number of sessions, duration of treatment, and specific tasks in each treatment session can be held constant across subjects and groups. All of these characteristics of laboratory investigations will minimize variability among subjects and therapists and increase the power of the test of a given intervention.

Laboratory investigations also allow the use of different control groups that might not otherwise be available. In laboratory research, specific ingredients of treatment, or indeed treatment itself, can be more readily withheld than in the clinical situation. Freedom in providing or withholding specific ingredients of treatment greatly expands the range of questions that can be asked about therapy. This perhaps is the greatest advantage of laboratory investigations of therapy.

The procedures used in laboratory investigations probably are more easily replicated than are those used in clinical investigations. In laboratory research, investigators can more carefully control and specify the parameters of treatment administration than in clinical situations. Subsequent investigators who wish to replicate the original laboratory study may have relatively explicit guidelines to follow because many parameters of treatment were well specified originally. In the clinical situation, all sorts of conditions must be allowed to vary and may not be easily repeated in subsequent research.

The superiority in control that laboratory research affords relative to clinical research is a function of the priorities of these different research methods. In laboratory research, which usually contains volunteer subjects rather than patients seeking treatment, the higher priority is given to the demands of experimentation. Sacrifices of treatment can be made to complete the requirements of the design. For example, the treatment can be standardized across clients rather than take into account individual differences with respect to the problem. In contrast, in clinical research with clients who have sought treatment, the higher priority is their improvement. Rigors of the laboratory may have to be sacrificed

to meet the priority of treatment. For example, the therapeutic material covered during the therapy session and duration of treatment may be allowed to vary widely so that clients receive sufficient treatment to affect the desired change.

To meet the rigors of experimentation, analogue research can be conducted in circumstances that resemble the clinical situations in varying degrees. The use of analogue studies has been widely discussed (e.g., Bernstein & Paul, 1971; Cooper, Furst, & Bridger, 1969; Cowen, 1961; Goldstein & Dean, 1966; Heller, 1963, 1971; Levis, 1970). These discussions have addressed the extent to which analogue studies are useful in understanding treatment in the actual clinical situation, the limitations of analogue research, and areas in which particular care may need to be taken in substituting experimental rigor for clinical relevance.

Conceptualization of Analogue Research

As usually discussed in the clinical literature, therapy investigations are looked upon as analogue or nonanalogue research. Yet, this may not be the most fruitful way to view clinically relevant research. Dichotomizing clinical research in this fashion may obscure interpretation of research findings in different ways. First, the distinction tends to overlook the inherent limitations and the "analogue" nature of all clinical research including those studies conducted in clinical settings with patient populations. Second, and more important for present purposes, the categorization does not provide clear guidelines to distinguish among analogue studies. Presumably, generality of the results from all analogue studies to the clinical situation is not equal and partially depends on specific characteristics of the individual study.

Virtually all psychological experimentation with human subjects is analogue research insofar as it constructs a situation in which a particular phenomenon can be studied. The phenomenon is selected as an approximation of the phenomenon in the nonexperimental situation. The experimental version of the phenomenon may resemble the naturally occurring phenomenon in varying degrees, but

in an important sense it is only an analogue.¹ It is assumed, and often supported, that the versions of the phenomenon in the experimental situation and "real world" are in important ways the same and come under identical principles and laws.

In human experimentation, the differences between experimental and nonexperimental situations may lead to important differences in subject behavior. These differences can readily alter the phenomenon that is being studied and the generality from the experimental to nonexperimental setting. For example, experiments with humans place subjects in a special situation and provide some form of intervention. Subjects may complete specific response measures before and after the intervention to assess change in particular responses. However, participating in an experiment or a contrived arrangement that is not normally encountered in everyday life makes the experiment an analogue of the situation to which one may wish to generalize the results. Indeed, such phenomena as demand characteristics of the experimental situation (Orne, 1969), subject roles (Weber & Cook, 1972), and pretest sensitization (Lana, 1969) are examples of the influences of experimental arrangements on behavior.

Even when the experimental situation is not contrived and does not differ from the situation in which the client normally behaves, other features of human experimentation contribute to its analogue nature. In an experiment, psychological measures (e.g., self-report inventories, behavioral checklists, physiological responsiveness) are used to assess the relationship between an intervention (e.g., treatment) and behavior change. Yet, it is not the response on the psychological measurement device per se that is of interest, but rather it is the construct that is assumed to be represented by the measure. For example, in clinical research in an actual treatment setting, a client's anxiety might be assessed with various devices. It is not the client's change on these

¹ Not all human psychological research is an analogue of the situation to which the investigator wishes to generalize. For example, research on the influence of the experimental situation itself on behavior is a direct test of the subject matter of interest.

measures per se that is of direct interest, at least to the client. These measures are of interest, because they may reflect or relate to changes occurring in the natural environment under ordinary circumstances. Insofar as experimental research uses measures that are considered to reflect or resemble the responses of clinical interest in the natural setting, it is an analogue of the situation of direct interest.

Viewing almost all psychological research with humans as analogues of situations to which one would like to generalize has important implications for conceptualizing treatment research. Initially, it is essential to keep in mind that investigators are interested in extrapolating the findings to some area, problem, or setting that is not studied directly. There is always the possibility that the extrapolation is not accurate in accounting for the natural phenomenon. The difference between the natural and experimental situation precisely along these (usually unknown) dimensions might lead to different findings for a given variable. A second implication is that it may not be useful to speak of analogue versus nonanalogue research. Rather, research can be viewed on the basis of the extent to which it resembles the situation to which one wishes to generalize the experimental findings. There are several dimensions along which therapy research may vary from the clinical situation that will be discussed below.

Experimental research usually is removed in some way from the situation to which one wishes to generalize. This by itself does not necessarily limit the extent to which results can be generalized. The results of studies often can be widely generalized across dimensions that may seem more discrepant than the leap from laboratory and clinical investigations in the area of therapy. For example, most findings in the psychology of learning have been obtained in experiments with infrahuman species. Specific learning paradigms and principles have had generality to human behavior despite differences between humans and infrahumans and the importance of considering uniquely human characteristics. Similarly, outside of psychology, infrahuman species have been used to study genetics. The laws that have been uncovered have applied to hereditary transmission in humans, even

though the population often studied (e.g., fruit fly) bears little resemblance to humans. As a general point, research conducted in the context of the laboratory under conditions that seem very distant from the one to which a researcher wishes to generalize may produce laws or generate theories of great relevance to areas that are not directly studied. Thus, the fact that a study does not focus on a problem and population of direct interest is not always critical.

Dimensions for Evaluating Therapy Analogues

In psychotherapy and behavior therapy research, the question of interest is not whether a particular study is an analogue. As noted earlier, experimentation even in the clinical rather than laboratory situation is removed from the actual phenomenon and situation to which one might wish to generalize. Thus, in any given therapy study, the question is to what extent the conditions resemble the situation to which the investigator wishes to generalize. This is a complex question, because there are a large number of dimensions along which studies may vary. Each study may be evaluated in terms of its standing on these dimensions to determine the degree to which the study approaches the clinical situation. Major dimensions that can be used to evaluate a study and the extent to which it is an analogue of the clinical situation include the target problem; the population; the manner of client recruitment; the therapists; the selection, set, and setting of treatment; the variation of treatment used; and the assessment procedures used.

Target problem. A major concern about the value of analogue studies, particularly in recent years, pertains to the target problem (Cooper et al., 1969; Levis, 1970). The issue is whether subjects in a laboratory study evince the same kinds of problems and the same magnitude of severity for a given problem as do the clients for whom treatment is usually provided. For example, in behavior therapy, a vast literature has appeared on the treatment of mild or subphobic levels of fear. Subjects typically are college students who express some level of fear on a questionnaire and

who refuse to approach a feared stimulus (e.g., harmless snake). The level of fear may be much less potent than one would encounter with a clinical population. Indeed, the percentage of subjects who meet the definition of "fearful" in laboratory studies vastly exceeds the percentage of debilitating fear for the same problem in the general population (cf. Bernstein & Paul, 1971). In any case, selecting mildly fearful college students raises the question of the generality of treatment effects to clinical patients whose fears (or other problems) are more intense. Certainly, the concern is well taken, because it should be easier to alleviate mild problems than it is to alleviate severe problems.

Aside from severity of a given problem, the specific behavior studied in therapy research may vary in topography and qualitative characteristics from clinical problems to which the results might be generalized. Some problems that have been frequently studied in laboratory research may bear little resemblance to clinical problems. For example, most behavior therapy techniques designed to alleviate anxiety have been evaluated with clients who fear small animals. Recent research has revealed that fears of small animals in college students typically habituate more quickly in response to the anxiety-provoking stimulus and are more influenced by suggestion than are fears in social situations (e.g., heterosexual anxiety, speech anxiety) (Borkovec, Stone, O'Brien, & Kaloupek, 1974; Borkovec, Wall, & Stone, 1974; Singerman, Borkovec, & Baron, 1976). Results from studies focusing on behaviors that do not rapidly habituate and are less amenable to demand influences are more likely to be generalizable to clinical problems that presumably share these characteristics (Borkovec & O'Brien, 1976).

The extent to which the target problem in a therapy investigation resembles clinical problems is a matter of degree. To obtain target problems that increasingly resemble the clinical problem, a researcher can screen for severity of the problem in a nonclinical population so that the subjects included in treatment experience some deleterious effects of their behavior in everyday life. Stringent criteria for subject selection make extrapolation of the findings to a clinical population much

more plausible. For example, Lang (1968), who conducted the earliest analogue studies of desensitization, indicated that only 1%-2% of college students will evince intense fear if rigidly screened on behavioral, interview, and self-report criteria. When treatment alters intense fears of college students who are stringently selected, it is not unreasonable to extend the findings to a clinical population.

Population. The characteristics of the population (subjects or clients) that receives treatment contribute to the degree to which an investigation is an analogue of the clinical situation. The population dimension encompasses all features that might distinguish subjects in an experiment from those for whom the results might be generalized. For example, in analogue fear studies common in behavior therapy, subjects often are college students. The study is an analogue of clinical treatment in the sense that college students as a group may differ on several dimensions from clinical populations typically treated for anxiety disorders in such characteristics as level of education, age, socioeconomic status, and occupation (or lack of one). The differences may bear directly on the effects of particular therapy procedures. For example, the age of the clients and situational characteristics of their lives may bear on the kinds of problems that they bring for treatment. The influences also may covary with the receptivity of individuals to professional treatment and to their expectancies for cure. The generality of findings from an investigation of treatment to a clinical situation may partially depend on the similarity of (nonproblem) characteristics of subjects to clients who usually come for treatment.

Manner of recruitment. In most treatment settings, clients solicit a therapist on their own or are referred by a particular source (e.g., physician, relatives). The manner of obtaining clients in therapy or institutional treatment differs markedly from the manner in which subjects are obtained in an experimental investigation of treatment. In many treatment studies, college students voluntarily participate in treatment because of small rewards toward college course credit, completion of a course option, or interest in learning about a specific form of therapy. Presumably, the in-

incentives for patients who directly seek out treatment through the usual channels differ drastically from the incentives of college students who may be less concerned with being "cured" of a particular problem. The volunteer patient and the mildly coerced college student who is not very much interested in the treatment or problem for which it is applied probably represent end points on the continuum of the extent to which a given therapy study is an analogue of a clinical treatment, at least on the dimension of manner of recruiting subjects. Perhaps, more toward the middle would be subjects who are solicited from newspaper, television, or radio advertisements that make available treatment to individuals in a community situation. This form of recruitment still solicits subjects, unlike most therapy situations. However, it is likely to uncover clients who are interested in treatment even though they would not have sought treatment without the advertisement.

The manner of recruitment also relates to the factors that keep a client in therapy. In clinical treatment, clients usually are free to terminate therapy and, indeed, readily do so without penalty. In treatment research in which attrition can be devastating to the results, specific contingencies can be invoked to retain subjects. For college students who participate in experimental treatment research, either explicit or implicit contingencies operate, such as withholding credit toward course completion until a project is terminated. With clients who are solicited for treatment, refundable deposits may be collected and returned later only if treatment has been completed. The threat of losing a refundable deposit significantly thwarts attrition (Hagen, Foreyt, & Durham, 1976). Clients in treatment usually pay for therapy and hence exert ultimate control over selection and termination of therapy. Although paying for therapy per se has not been found to influence therapeutic outcome, it does covary with other variables such as diagnosis and socioeconomic status that do (Pope, Geller, & Wilkinson, 1975). In any case, the different contingencies that maintain clients in treatment may influence the generality of findings across laboratory and clinical settings.

Therapists. In the clinical situation, an

experienced therapist usually provides treatment. On the other hand, experienced full-time therapists are infrequently used in most therapy research, although there are outstanding exceptions (e.g., Orlinsky & Howard, 1975; Paul, 1966; Sloane et al., 1975). Typically, graduate students with some interest or experience in clinical applications serve as therapists. The similarity of students to therapists who apply therapy techniques in clinical situations is a dimension that may determine the extent to which the results can be generalized from research to practice.

The therapist dimension is complex, because it may include multiple differences in the characteristics of individuals who provide treatment (see Meltzoff & Kornreich, 1970; Truax & Mitchell, 1971). Initially, student therapists and professional clinicians may differ on such variables as experience, training, age, and other characteristics. In addition, they may behave differently toward their clients. Therapists may engage in certain types of conversation, hold greater expectations for improvement, and have a stronger commitment to patient cure than do students serving as therapists. The generality of treatment effects in a therapy study to the clinical situation may depend in part on who serves as therapists.

Selection, set, and setting of treatment. In clinical work, clients seek a particular treatment that they believe will be effective. Independently of how well the technique in fact helps people, the set with which people arrive at treatment is that they will receive a bona fide treatment designed to alter their behavior. In addition, the client may have heard about the particular treatment and therapist with whom he or she will have contact. The assignment of clients to treatment may be selective, since individuals exert some choice over treatment. If treatment is not viewed favorably by a client after having attended some of the sessions, choice can be exerted by leaving and attending another treatment. In experimental therapy research, clients often are assigned to treatment and are not given a choice over the treatment or therapist. The element of choosing or seeking out a particular treatment may influence the generality of results obtained in therapy

research. Indeed, therapy investigations have indicated that being able to choose treatment is highly related to therapeutic outcome, independently of the specific technique that is actually received (Devine & Fernald, 1973; Gordon, 1976).

The client's set about treatment, perhaps related to choice and selection mentioned above, may contribute to the generality of results from treatment research to clinical applications. The set about receiving an effective treatment is likely to be enhanced by the aura of the treatment facility or office and by the convincing description of therapy provided by the therapist (Frank, 1973). Interestingly, the set of the client when arriving at treatment and the manner of presenting treatment may differ markedly across research and clinical settings. In the research setting, the client may not have the initial set that an effective treatment will be provided. Also, the actual setting (e.g., university building rather than a clinic) may not foster the set for receiving help with one's problem. In addition, instructions on the part of the investigator may indicate that the procedure to be used is an "experimental" treatment.

In recent years, ethical standards for research increasingly have stressed that investigators should explicitly convey the nature of the treatment, whether it is experimental in nature, and the possible benefits and risks. The procurement of informed consent in the context of experimental clinical research may alter to some extent the manner or context in which treatment is provided. In ordinary therapy, patients usually are not told that treatment is experimental but rather are given a convincing rationale about its efficacy and illustrations of other cases. In contrast, "experimentation" usually conveys the exploratory nature and tentative effects of treatment. Generalizing the results from research to the clinical situation depends in part on the similarity of the manner in which treatment is presented and the sets of the individuals who participate in treatment.

The dependence of treatment effects on the context in which treatment is presented was demonstrated clearly by Bootzin (Note 1) in a laboratory study designed to alter fear

of rats in college students. Bootzin compared live modeling (observing someone perform a fearless response, touching and holding the rat) versus live modeling plus participation (observing plus actually engaging in touching and holding of the rat). For one half of the subjects in each of these groups, the experience was called a "treatment" demonstration; for others, the experience was labeled as a maze learning demonstration (since the rats eventually were run through a maze at the end of the session). Interestingly, live modeling plus participation decreased fear of rats (on an assessment battery administered outside of the context of this experiment) whether or not subjects were told that the demonstration was "treatment for fear." In contrast, subjects who received live modeling showed a reduction of fear only if they served in the group that specifically identified the procedure as treatment. Thus, the effectiveness of modeling depended on being identified as a form of treatment, whereas the effectiveness of modeling plus participation did not.

The general point here is that the context in which the procedures are presented may differ across studies and distinguish the specific effects of treatments. This creates some obvious problems for research that often cannot present the treatment program with the same amount of zeal that might be the case in actual clinical practice.

Variations of treatment. The extent to which the results of a therapy study can be generalized to the clinical situation depends on the degree to which the actual treatment is varied across research and clinical applications. Occasionally, changes are made in specific components of treatment to increase precision in research, to control variability across subjects, or to examine a component of treatment that might be difficult to study without the variation. Even though some changes may pertain to ancillary features of treatment, others might represent significant departures.

Several components might vary across the research and clinical versions of a given treatment. For example, research applications may hold constant the number of treatment sessions across groups; the duration of treatment sessions; the material, tasks, or topics dis-

cussed within sessions; and so on. These dimensions usually are not specified in clinical applications, and they vary freely. Yet, in research the dimensions may be rigidly specified to ensure that they do not systematically vary across treatment conditions or subjects within a condition.

Some of the components may be more important than others in standardizing treatment to make it well suited to the demands of research. For example, portions of treatment in an experiment may be prerecorded and presented by tape to the client. Perhaps, more seriously, standardization of an aspect of treatment may change a crucial ingredient of therapy that would vary treatment efficacy. For example, in systematic desensitization, clients imagine specific scenes to overcome anxiety. These scenes are hierarchically arranged and individually tailored to a client's problem. In clinical research in which specific components of treatment are standardized across groups, individuals may receive the same hierarchy of items based on the assumption that it will be germane and approximately suited to their individual needs. Yet, technically, this is a violation of the original requirement of treatment. Traversing items that are not designed for a given individual violate the goal of minimizing anxiety throughout treatment and of ensuring that relaxation is the dominating response during imagery.

Perhaps an even more extreme departure from clinical treatment is the use of slides presented to the subject as part of desensitization rather than having the client imagine the scenes (e.g., Brown, 1973; Wilson, 1973). While the client is relaxed, the slides are to be viewed as an analogue version of desensitization in which imagery is paired with relaxation. The use of slides represents a major procedural variation of treatment. Yet, this variation is consistent with the original theoretical rationale, which suggested that fear stimuli, however presented, and an incompatible response need to be paired (Wolpe, 1958). In general, many sources of departure exist that could decrease the resemblance of research and clinical versions of treatment.

Assessment procedures. The extent to

which a therapy investigation resembles the clinical situation is influenced by diverse aspects of the assessment procedures including the reactivity of assessment, the setting in which assessment is conducted, and the precise measures used. To begin with, the client's problem behavior usually is measured in situations in which the client is fully aware of the purposes of assessment. Reactivity or awareness of the assessment process itself may influence the type of information obtained about the client's behavior. Once aware of assessment, the client's responses might be influenced by response sets, biases, and demands of the situation that cue certain types of responses (Bernstein, 1973). The goal of therapy is to change behavior in the client's everyday performance that is not under the scrutiny of a psychologist. Demonstrations of behavior change on reactive measures that are under the scrutiny of a psychologist may only be a distant approximation of the relevant changes that the client wishes to achieve. The extent to which a study measures everyday performance in social situations or approximations of that performance may determine the generality of results to clinical situations.

Part of the artificiality of assessment derives from the setting in which the effects of treatment are evaluated and the specific assessment devices used. Consider first the setting and the contribution it makes to evaluating behavior change. Several studies have demonstrated the effect of the setting in which behavior is assessed by having subjects perform in the context of a "clinic" versus a laboratory setting (Bernstein, 1973; Bernstein & Nietzel, 1973, 1974). The actual physical setting is not the crucial ingredient. Rather, the clients are told that assessment is taking place in a clinical setting as part of a treatment program or in a laboratory setting as part of a program unrelated to therapy and treatment of behavior. The studies have shown that clients evince more severely problematic behavior in the laboratory setting. Thus, the set and setting contribute to the assessment results.

A related assessment problem pertains to the precise measures used to assess client behavior. The measures commonly used to eval-

uate therapy effects are paper-and-pencil inventories of specific psychological traits or states (e.g., anxiety), global self-evaluation, samples of direct behaviors, or physiological responses. Although these measures might well reflect change, they vary in the extent to which they reflect the problem for which the client may have sought treatment. As mentioned earlier, clients do not seek treatment because of the severity of a problem as reflected on *psychological measures*. Yet, it is these measures that are used to evaluate treatment. The extent to which a study contains measures that relate to the situations in which the client expresses his or her problem is important in generalizing the results of the study to the clinical situation.

The use of direct behavioral samples in contrived situations, if clients have complained of specific problematic behaviors, may approximate the clinical situation. For example, drinking of alcoholics has been assessed in inpatient treatment settings in which clients can sit and consume alcohol at a simulated bar (e.g., Sobell, Schaefer, & Mills, 1972). This might appear to be a close approximation of the clinical problem of drinking outside of the laboratory. However, it is still relatively distant from nonlaboratory situations. Indeed, reports suggest that alcoholics drink infrequently in treatment facilities when alcohol is made available (Skoloda, Alterman, Cornelison, & Gottheil, 1975). Apparently, many of the psychological cues of the natural environment (e.g., work demands, interactions with one's spouse) rather than physical cues of the drinking situation may precipitate drinking (Lawson, Wilson, Bridgell, & Ives, 1976). Thus, a method of assessment that reflects the behavior even more directly than a laboratory approximation would be more representative of clinical change. Alcohol consumption sampled at random periods in the client's natural environment would provide a more direct measure of the clinical behavior (e.g., Miller, Hersen, Eisler, & Watts, 1974). If alcohol consumption is assessed in the original situation in which the behavior is problematic, this is not an approximation of the clinical problem but a direct reflection of the problem itself. In any therapy investigation, it is important to

evaluate the extent to which the response measures approximate the client's problem and the manner in which assessment is conducted.

Degree of Resemblance to Clinical Situations

The above discussion outlines dimensions along which therapy investigations can vary. The list of dimensions is not necessarily exhaustive. The importance of the discussion does not derive from the specific dimensions enumerated. Rather, the value derives from viewing treatment investigations as multidimensional. The generality of the results of an experimental investigation of treatment depends on where the investigation lies with respect to these and similar dimensions vis-à-vis the clinical situation.

Each of the dimensions, and occasionally separate aspects of a given dimension, can be viewed as a continuum along which studies can vary. The continuum reflects the degree of resemblance of the study on a given dimension to the clinical therapy situation to which the results are to be generalized. The continuum for a given dimension ranges from identity with or close resemblance to the clinical situation to little or no resemblance to the clinical situation. In more commonly used terms, the continuum might be analogous to classifying the study as clinical (or applied) versus laboratory (or basic) research. However, this classification is an oversimplification, because it does not treat individually the different dimensions along which a study can vary and be evaluated.

If each of the dimensions mentioned earlier is viewed as a separate continuum along which the study might be evaluated, the task of evaluating an analogue study depends on where it falls on the continuum with respect to each dimension. Also, the extent to which the results of the study can be generalized depends on how the dimension relates to treatment efficacy. The issue here is how to decide the generality of the results of a study that in some way only resembles the clinical situation.

An explicit assumption in the therapy literature is that the degree to which a study resembles a clinical situation (for a given

dimension) indicates the likelihood of its generality to the clinical situation. Consider the dimension of severity of the target problem as one means of evaluating a therapy study. One would expect that a treatment shown to be effective in changing mildly problematic behavior (e.g., mild fear in college students) might have little generality to a more severe degree of similar behavior (clinical phobias). This is a very reasonable expectation and indeed might be bolstered with support from literature from both psychotherapy and medicine. For example, individuals who experience relatively severe insomnia do not respond as readily to placebo treatment as those who experience relatively mild or moderate insomnia (Nicolis & Silvestri, 1967). More generally, a concern in evaluating treatment is that less severe behaviors can be readily changed, whereas severe clinical problems cannot. This concern is the primary objection to analogue studies in behavior therapy in which the efficacy of select techniques occasionally has been based on the treatment of relatively mild problems (cf. Bernstein & Paul, 1971).

As a general rule, beyond considering only the target behavior dimension, an implicit assumption often made is that the greater the resemblance of a treatment investigation to the clinical situation, the more difficult it will be to change behavior. Changing behavior is considered to be increasingly difficult as the investigation departs from well-controlled laboratory analogue conditions and approaches characteristics of the clinical situation.

With many dimensions, it is possible and indeed likely that the assumed relationship is accurate. Thus, studies that only faintly resemble the clinical situation could readily produce changes that are not likely to be generalized to the clinical situation. However, with other dimensions, it is quite reasonable to expect that the results may be quite generalizable from laboratory to clinical settings. Possibly, the *less* resemblance of the study to the clinical situation for a given dimension, the *more* difficult it would be to change behavior. That is, departure from the clinical situation may make behavior change more difficult to achieve. In these cases, dem-

onstration of behavior change in the nonclinical situation might be a more convincing demonstration of an effect of treatment than would application in the clinical situation. For example, consider the *therapist* dimension. If therapists who bear very little resemblance to those who normally practice therapy (e.g., show less experience, education, and training) effect marked behavior change in their clients, the generality of this finding to highly trained therapists would be quite plausible. One might expect that if therapists who were actually untrained high school students, for example, could effectively change behavior, the effects would be likely to apply at least as well to trained professionals.

Similarly, consider the *treatment* dimension; if behavior change is shown with a variation of treatment that deviates from the clinical version, this does not necessarily mean that the results might not be generalized to the clinical version of the treatment. In many cases, the laboratory version of treatment is an important test of clinical treatment, because it minimizes the parameters of treatment that are likely to contribute to change (e.g., individualization of treatment, deviations from the treatment rationale to handle individual subject problems, etc.).

Finally, consider the *client* dimension. Clients who normally seek treatment in a clinical setting are likely to be experiencing some sort of crisis (i.e., defined as severity of the symptoms or behavioral problem) that precipitated seeking help. In this state, clients who seek help may be particularly motivated for and receptive to treatment and therefore hold high expectancies for improvement. This may make clients show improvements even before or very early in treatment (e.g., Frank, Nash, Stone, & Imber, 1963; Goldstein & Shipman, 1961). In addition, in the clinical situation, clients may be likely to comply with therapeutic instructions and perhaps even accept the treatment rationale relatively uncritically. Although all clients who seek treatment are not desperate for relief, severity of the problem should increase the incentive for attending and adhering to therapy.

At the other end of the continuum might be college students recruited for a treatment study with inducements of course credit. The

incentives for obtaining help and for complying with the requirement of treatment may be less than for clinical patients. If a given treatment effects change in subjects who are less motivated and who in fact adhere less rigorously to treatment requirements (e.g., do not perform "homework" assignments as conscientiously) than do clients in a clinical situation, then the effects of treatment could be more pronounced in a clinical situation.

The purpose of the present article is merely to raise the possibility rather than to assert that the analogue situation may occasionally provide a more rigid and more conservative test of a relationship between treatment and therapeutic change than that provided in the clinical situation. This is reasonable to entertain, because laboratory studies may dilute aspects of treatment that are central to behavior change. In these cases, the commonly assumed relationship between behavior change and the lack of resemblance of the study to the clinical situation is altered.

A problem in clinical research is that analogue research has been rejected by many on the grounds that by its very nature, it provides a weak test of the relationship between a variable and change in the clinical situation. Yet, this is not necessarily the case.

The relation between an analogue study and generality to clinical situations for a given dimension itself is an area of research. The importance of a given dimension (e.g., population, therapists, manner of recruitment, etc.) to the generality of the results needs to be evaluated directly. Increasing resemblance of a given dimension of a study to the clinical situation may not necessarily predict the extent to which the results apply to the clinical situation. In advance of studies showing this relationship, this assumption across all of the dimensions reviewed earlier should not be made.

The generality of results of a given study can only be evaluated directly by studying the variables of interest in the clinical situation itself. Thus, research always needs to test out the variables, insofar as possible, in the actual situation. However, the value of analogue research in understanding clinical phenomena can be partially evaluated

prior to direct clinical tests of individual findings. Research is needed that investigates the influence of departures from clinical situations along various dimensions and the implications of such departures for generalizing results to clinical situations. The effects of varying degrees of resemblance to the clinical situation for a given dimension need to be evaluated on therapy outcome. Comparisons of different points on a continuum varying in degrees of resemblance can reveal whether departure from the clinical situation for a given dimension attenuates, enhances, or has no effect on treatment. Once these relationships are elaborated, the generality of findings from research to clinical situations can be more easily evaluated for laboratory-based treatment studies.

Conclusion

Analogue therapy research has proliferated in recent years, especially in the area of behavior therapy. Extensive research has led to an empirically based methodology of carefully studying treatment procedures and parameters that influence behavior change. Yet, many authors have raised questions about the relevance of analogue work to the clinical situation and have suggested specific procedures to increase the similarity of treatment research to clinical applications (e.g., Bernstein & Paul, 1971; Borkovec & O'Brien, 1976). Research in psychotherapy and behavior therapy can differ from the clinical application of treatment along several dimensions such as the target problem, the clients and the manner in which they are recruited, the therapists, the selection of treatment, the client's set, and the setting in which treatment is conducted, the variations in treatment, and the assessment procedures used.

For evaluating the generality of research findings to the clinical situation, the main question of interest is not whether the investigation is an analogue of the clinical situation. An investigation invariably will be an analogue by the very nature of experimental research. *The alternative questions of interest seem to be the extent to which treatment research deviates from the clinical situation, along what dimensions, and whether the man-*

ner in which there are differences makes research a relatively strong or weak test of treatment in relation to the likely results in a clinical situation.

The primary purpose of the present article was to suggest a methodology for studying generality directly. Laboratory analogue research may differ from clinical treatment along several dimensions. Each dimension is a continuum spanning from little or no resemblance of the study to the clinical situation to close resemblance or identity with the clinical situation. Each investigation of treatment can be classified separately on several dimensions denoting its resemblance to the clinical situation. *Increasing similarity of an investigation to the clinical situation for a given dimension does not necessarily argue for greater generality of the results from the research to the clinical setting. Whether standing of a study on a given dimension is relevant to generality of the results needs to be determined empirically.* Laboratory treatment research that differs from clinical treatment may not necessarily provide a less stringent test of treatment. Indeed, for some dimensions, laboratory research may provide a more conservative test, and changes found in the laboratory may be even more likely to obtain in the clinical setting. However, the purpose here is not to speculate or make assumptions about the extent of generality of the findings of a study. It is hoped that dimensions that may affect generality will be subject to empirical scrutiny.

Methodological Considerations in Treatment Outcome Research on Obesity

G. Terence Wilson
Rutgers—The State University

Although there has been a dramatic increase in treatment research on obesity, numerous methodological inadequacies continue to obstruct further development of the field. Specific problems are identified, and corrective procedures are outlined. The importance of multiple measurement of outcome, including appropriate assessment of weight, activity, and relevant physical, emotional, and social indices of adjustment, is emphasized. Traditional evaluation criteria need to be broadened to encompass factors such as cost effectiveness of treatment. The relative merits of alternative single-subject and between-groups experimental designs are discussed, the latter including the treatment package, constructive, dismantling, and comparative research strategies. Ways of controlling for non-specific treatment influences are reviewed, and the contribution of client and therapist variables to outcome are mentioned. The reasons for conspicuous lack of long-term follow-ups are analyzed, and recommendations for reducing subject attrition during treatment and follow-up are advanced.

It was only 10 years ago that Stuart (1967) reported his findings on the behavioral treatment of overeating. Over the years that have followed this landmark publication, we have witnessed a dramatic upsurge of interest and research activity in the behavioral treatment of obesity. Research reports, evaluative reviews, books, and audiotape cassettes on the treatment of obesity seem to be appearing at an ever-quicken pace. Less evident but nonetheless revealing of this trend are the numerous manuscripts that are increasingly submitted to the psychological journals but that are rejected on the basis of one or other methodological problem. In short, as Jeffery, Wing, and Stunkard (1978) observed, behavioral treatment of obesity has attained a popularity among professionals that verges on faddism.

These developments in the treatment of obesity are attributable to several factors. In part, they reflect a more general phenome-

non, namely the extraordinary growth of behavior research and therapy as a whole (cf. Franks & Wilson, 1973, 1977; Hoon & Lindsley, 1974). The fact that obesity has been a subject of intensified research interest within the wider context of the development of behavior therapy is not surprising. Unlike most other clinical problems that have been the focus of treatment outcome research, obesity offers a definitive yet convenient and objective measure of outcome efficacy—weight reduction. Instead of the all-too-familiar difficulties inherent in the measurement of other clinical disorders, such as rating anxiety, inferring depression, judging interpersonal adjustment, or estimating alcohol consumption, a quantitative measure is obtained by simply asking the obese client to step on a scale. Furthermore, unlike most other behavior disorders, large samples of obese subjects for research investigations are readily available. Finally, largely as a result of historical accident—Stuart's (1967) influential application of the principles and procedures initially proposed by Ferster, Nurnberger, and Levitt (1962)—weight reduction has become an important arena for the eval-

uation of behavioral self-control methods. The happy combination of a handy, "hard" index of treatment outcome for large numbers of motivated subjects who can usually be recruited at minimal effort and cost and who provide a made-to-measure testing ground for one of the hottest areas of behavioral modification has proven irresistible to behavioral researchers.

These circumstances have encouraged behavioral research on obesity. However, the ostensible ease with which controlled research can be conducted with obese clients has also helped spawn countless studies that have contributed neither to our knowledge about the treatment of obesity in particular nor to the development of the principles of behavior change in general. Many of these studies have been master's degree theses or doctoral dissertations in psychology. In contrast to those well-designed, thoughtful, and often time-consuming and effortful doctoral research projects that have advanced our knowledge, a large number of studies are reeled off more because of the convenience than for any other reason. Indeed, on the basis of several years of reviewing manuscripts for this and other psychological journals, I argue that short-term "quickie" studies on the behavioral treatment of obesity are now almost on a par with so-called "analogue" studies of snake-fearful college students as part of the staple diet of investigators seeking mainly to satisfy degree requirements and/or bolster sagging publication records. This practice, together with other largely unacknowledged influences discussed more fully below, have contributed directly to two of the major shortcomings in the field, namely, the paucity of long-term follow-up evaluations of treatment programs and the predominance of treatment findings that are frequently statistically but not clinically or substantively significant.

The present article is an attempt to describe some of the more common methodological inadequacies in research on the treatment of obesity and to suggest alternative, improved strategies for future evaluations. Research on the "new obesity therapy" has been accompanied by renewed investigation of presumed differences in eating patterns in obese

and nonobese populations; however, this article focuses on treatment outcome considerations. Although the issues raised in the following discussion have broad relevance to the evaluation of all treatment outcome research on obesity, the particular focus is on behavioral approaches.

Measurement of Treatment Outcome

Weight Loss

As stated above, the availability of an objective measure of weight loss was a *raison d'être* for the application and evaluation of behavioral principles in the modification of obesity. However, some studies, mostly those of a nonbehavioral nature, still fail to report specific information on weight loss, the custom being to report general impressions of changes in subjects' personal adjustment and emotional well-being (cf. Leon, 1976). The importance of gathering multiple measures of subjects' response to treatment is emphasized below. Yet, regardless of whatever other outcome measures are obtained, direct assessment of weight loss is a *sine qua non* of adequate evaluation of treatment of obesity. Neglecting to report precise data on weight in favor of a discussion of inferred psychological changes obfuscates evaluation of treatment efficacy and, as Bandura (1969) cautioned, can easily result in the "perpetuation of weak methods on the basis of extraneous criteria" (p. 540).

Although it is necessary that specific weight loss be reported, it is not sufficient. Clearly a 40-pound (18 kg) weight loss in a 400-pound (181.6 kg) individual is not the same as a 40-pound weight loss in a 160-pound (72.7 kg) individual. Following Stunkard and McLaren-Hume (1959), several studies have reported results in terms of percentage of subjects who lose specified amounts of weight, for example, more than 10 (4.5 kg), 20 (9.0 kg), 30 (13.5 kg), or 40 pounds, respectively. It is difficult to interpret these figures in the absence of precise information on subjects' initial weights. Musante (1976), for example, reported treatment outcome according to clients who lost more than 20 pounds or 40 pounds, respectively. Initial weights, however, ranged as widely as 155–484 pounds (70.5–

197 kg) in males and 125–321 pounds (56.8–145.9 kg) in females. As others have noted (cf. Hall & Hall, 1974; Jeffrey, 1975), simply reporting absolute weight loss severely impedes meaningful comparisons among different studies. Comparative analyses of the outcome of different studies requires the use of a standardized measure of improvement. Change in percentage overweight is more informative than absolute weight loss, since it takes initial weight into account. Better still is the weight reduction quotient (cf. Feinstein, 1959), which measures the amount of weight loss relative to the amount needed to obtain an ideal target weight. Specifically, the weight reduction quotient is a function of Relative Initial Overweight \times Percent of Surplus Weight Loss:

$$\text{weight reduction index} = \frac{\text{pounds lost}}{\text{pounds overweight}} \times \frac{\text{initial weight}}{\text{ideal weight}} \times 100.$$

This index takes account of height, amount overweight,¹ weight reduction goals, and absolute pounds lost. Several studies have used a truncated version of this index, namely,

$$\frac{\text{pounds lost}}{\text{pounds over ideal weight}} \times 100,$$

which reflects percentage of weight goal attained (e.g., Ashby & Wilson, 1977; Brownell, in press; Kingsley & Wilson, 1977; Mahoney, 1974). The complete formula compensates for the fact that the obese person has to lose more absolute weight to attain the same percentage of his or her target weight goal.

Both measures of weight—absolute weight loss and the reduction quotient—should be reported in treatment outcome studies. These two measures have yielded essentially similar patterns of results in several studies to date (e.g., Ashby & Wilson, 1977; Green, in press; Kingsley & Wilson, 1977; Mahoney, 1974). However, Brownell (in press) found a discrepancy between the two measures. Differences among treatment groups that were statistically significant in terms of absolute weight loss and change in percentage overweight were not statistically significant in terms of percentage of target weight goal attained.

Weight measurements should be based on specific readings obtained by the investigator using a reliable scale. Until the validity of self-reports of weight loss is established, individuals' estimates of their own weight gathered over the telephone (e.g., Hanson, Borden, Hall, & Hall, 1976) or through the mail (e.g., Mahoney & Mahoney, 1976) are less desirable and must be viewed with appropriate caution.

Treatment outcome measures based on weight have been criticized as true measures of obesity, that is, excessive body fat (LeBow, 1977). Overall weight reflects the person's total body mass, which includes the musculature and water composition in addition to body fat. Body weight might be a good predictor of body fat in very overweight individuals, but the relationship is less clear for minimal or moderate degree of overweight. Body weight is an especially poor index of body fat in young children, the elderly, and when comparisons are made among different age groups (Mahoney, Rogers, Straw, & Mahoney, in press). Since it is body fat that is presumably the target of obesity treatment programs, indices other than weight that specifically measures body fat have been advocated. Changes in body weight might confound reductions in body fat with the effects (usually temporary, however) of diuretics and laxatives. The use of skin-fold measures may provide a better predictor of body fat provided that precautions are taken to ensure reliability (Franzini & Grimes, 1976; Johnson & Stalonas, 1977) as a reliable and valid index of body fat. For these reasons, future outcome research might profitably include specific measures of body fat in addition to changes in body weight.

Objective Measures of Eating Behavior

There are instances in which the direct measurement of specific eating behaviors of food

¹ Ideal weight is usually based on the 1959 Metropolitan Life Insurance Company norms (U.S. Department of Health, Education and Welfare, 1967). Less frequently used are actuarial data of height and weight by age in a U.S. Department of Agriculture report (Hathaway & Foard, 1960). Seltzer (1965) discusses the limitations of such height-weight tables.

consumption patterns rather than changes in weight is of primary concern. Some examples and measurement strategies can be briefly noted. For example, Diamant and Wilson (1975) evaluated the efficacy of a particular behavioral treatment technique, covert sensitization, in decreasing consumption of a specific target food. Weight loss was too molar a dependent variable for this purpose, since it is a function of several variables that are not specifically affected by covert sensitization. Thus covert sensitization might decrease an individual's consumption of a particular food but not ensue in weight loss, because the individual increases consumption of other foods that were not targeted in the treatment. The efficacy of that technique would be obscured. This would be unfortunate, because if a specific method could be shown to be effective in reducing specific consumption of a particular food, then it might be extended to decrease other excessive eating habits or included in a broader treatment program that has as its aim the modification of obesity as such. On the other hand, if the technique is shown to be ineffective, then it can be dropped from multifaceted treatment programs. Accordingly, Diamant and Wilson (1975) adapted the taste-rating task from Schachter, Goldman, and Gordon (1968) as a direct laboratory measure of the consumption of specific target and nontarget foodstuffs rather than rely solely on subjective ratings of specific food preferences as an outcome measure of the effects of covert sensitization. (Some of the methodological considerations governing the use of the taste-rating task as an index of treatment outcome were raised by Leon & Roth, 1977; see also Nathan & Briddell's 1977, discussion of the assessment of alcohol consumption.)

The taste-rating task is a laboratory measure of eating behavior under controlled conditions. Measurement of food consumption in the natural environment is achieved by unobtrusive behavioral observations. Epstein, Parker, McCoy, and McGee (1976) and Gaul, Craighead, and Mahoney (1975) provide illustrations and discussion of the use of systematic behavioral observation as a means of assessing eating under natural conditions.

Direct Indicators of Cardiovascular Health

Mahoney et al. (in press) have criticized the almost exclusive reliance of treatment outcome studies on body weight. They suggest that more attention be given to factors that are directly related to cardiovascular health, for example, blood pressure, serum lipids (particularly triglycerides), and activity. The importance of exercise components has often been deemphasized in weight reduction programs. In lieu of less practical procedures, activity level can be assessed and caloric expenditure can be estimated on the basis of subjects' self-monitoring.

Criteria For Evaluating Treatment Outcome In Obesity

In addition to the specific measurement considerations discussed above, there are broader issues that bear on the evaluation of treatment programs for obesity. These issues include both client-related and efficiency and cost-related criteria for outcome evaluation.²

Clinical Significance of Treatment Effects

As noted above, the fact that the evaluation of behavioral methods rather than the treatment of obesity per se has frequently been the primary purpose of experimental investigations has resulted in findings that are statistically but not necessarily clinically significant (cf. Stunkard & Mahoney, 1976). Yet, in clinical research a major criterion for evaluating therapy is the overall importance of the treatment-produced improvement. The clinical significance of amount of weight reduction can be considered to be of comparable importance to the statistical comparison of group differences. The magnitude of weight loss needs to be given much more attention in the future treatment literature.

Proportion of Clients Who Improve

Designs that emphasize statistical comparison of group differences average the amount of weight reduction across all subjects within

² See Kazdin and Wilson (1978) for a more detailed discussion of these broader criteria for the evaluating treatment outcome in general.

each treatment group. This tends to obscure individual differences, a consequence of particular importance in the treatment of obesity in which massive interindividual variability has been one of the most consistent findings in the literature (cf. Jeffery et al., 1978; Penick, Filion, Fox, & Stunkard, 1971). Two different treatment methods might result in significant improvement in a greater proportion of subjects while some subjects show an increase in weight. For example, Penick et al. (1971) found considerably greater variability in weight losses in their subjects treated with behavior modification than in subjects treated with traditional psychotherapy. The five most successful subjects, as well as the single least improved subject, were in the behavioral treatment. Since a particular treatment might be recommended on the basis of the proportion of treated clients who are likely to show some specified improvement rather than on the basis of a group average, reports of treatment studies should indicate the number of individuals who lose clinically significant amounts of weight. Rather than simple categories of absolute pounds lost (e.g., Stunkard & McLaren-Hume, 1959), however, an index of weight corrected for initial relative obesity would be preferable. More specifically, given the recurring interindividual variability in treatment outcome that has yet to be adequately explained, it is suggested that individual data be reported even in the context of between-group designs (e.g., Aragona, Casady, & Drabman, 1975).

Multiple Measures of Change

In addition to the primary measure of weight loss, treatment studies should include concurrent evaluation of subjects' physical, emotional, and social functioning (Coates, 1977). For example, a therapeutic method might decrease weight but result in adverse side effects. To take an extreme example, even if a surgical intervention such as the jejunoileal bypass operation were effective in decreasing weight, its numerous serious side effects might contraindicate its use, especially cases of moderate obesity (cf. Chlouverakis, 1975). Treatment approaches that might be equally effective in decreasing weight might

produce sufficiently different side effects so as to recommend one over the other.

In one of the rare comparative studies that has addressed this issue empirically, Öst and Götestam (1976) reported that a pharmacological treatment (fenfluramine) produced more frequent and more protracted negative side effects than a behavioral treatment program. Stunkard and Rush (1974) have described the occurrence of depression concomitant with weight loss in clients receiving traditional psychotherapy. The theory that obese adults who lose weight fall below a biologically dictated "set point," and that as a result they enter a state of chronic energy deficit, specifically predicts adverse emotional reactions such as depression and irritability as a function of continued weight loss (cf. Nisbett, 1972). Yet the results of behavioral treatment programs have indicated no such effects. On the contrary, weight loss in behavioral programs has been associated with positive consequences for emotional and social adjustment (e.g., Stuart, 1967, 1971; Wollersheim, 1970). Adverse side effects of behavioral treatment techniques that produced weight loss have been noted. Contingency contracting resulted in significant weight loss, but closer analysis revealed that subjects adhered to the externally imposed reinforcement system by resorting to a variety of potentially hazardous procedures such as the use of diuretics, vomiting, starvation, and steam baths (cf. Mann, 1972). Contingency contracting has also been reported to increase absences from therapy sessions (Jeffrey, 1974) and other undesirable behavior (Mahoney, Moura, & Wade, 1973).

On the other hand, clients who do not lose significant amounts of weight might nonetheless show improvement in other areas of life functioning. Specific subjective and objective measures of the breadth and nature of the changes associated with the treatment for obesity will shed light on these potentially important relationships among different response systems.

Efficiency and Cost Effectiveness

Magnitude of weight reduction is not the only criterion for evaluating treatments for

obesity. The efficiency of treatment, including its duration, ease of administration, and disseminability, needs to be taken into account (cf. Kazdin & Wilson, 1978). Determining the cost effectiveness of treatment is particularly important given the availability of alternative treatment approaches of roughly comparable efficacy in producing weight reduction. Jeffrey (1975) has proposed a useful cost effectiveness index that is a function of the mean weight reduction quotient divided by mean treatment time per client. The financial cost of treatment is influenced by the costs of the professional training of the individuals who conduct treatment and the disseminability of the methods. In addition, the emotional cost experienced by the client in participating in a treatment program might be assessed. For example, procedures such as starvation diets and surgical interventions can be contrasted with behavioral methods that emphasize gradual weight loss over an extended time period by reducing overall caloric intake without prescribing any fixed diet. Consumer (client) evaluation of treatment would provide useful information about the acceptability of different methods. Some treatments might be inherently objectionable irrespective of financial cost or even outcome efficacy.

Experimental Design and Research Strategies

Treatment outcome research on obesity has consisted predominantly of between-group designs of one sort or another, although single-subject methodology has also been used. Each of these two contrasting research strategies includes several alternative methods replete with different methodological advantages and disadvantages.

Single-Case Experimental Methodology

Single-case experimental designs focus on therapeutic change in the individual client rather than average change across groups of clients. The defining characteristics of the designs include the observation of overt behavior, continuous assessment of change, and specific criteria for evaluating the reliability and significance of treatment-produced change

(see Hartmann & Hall, 1976; Hersen & Barlow, 1976; Kazdin, 1973).

There are several reasons why single-subject designs seem suited to research on the modification of obesity. First, the emphasis on the individual subject seems particularly appropriate given the repeated finding, noted above, of considerable interindividual variability in treatment outcome studies on obesity. Second, weight loss provides an observable and easily measured target behavior. And finally, single-subject methodology contains a therapeutic criterion for evaluating the clinical importance of behavior change. Specifically, this criterion emphasizes the magnitude of weight loss and the extent to which treatment brings the individual within acceptable or normative levels of body weight. This characteristic assumes special importance given that a major criticism of treatment studies has been the failure to demonstrate clinically meaningful reductions in weight as opposed to statistically significant comparisons among different treatment groups.

Some examples of the surprisingly few single-case experimental designs in the treatment of obesity can be briefly noted. Mann (1972) used an ABAB reversal design in demonstrating that contingency contracting can result in substantial weight losses. Weight loss occurred only when the contingency contracting procedure was in effect. Subjects lost no weight or even gained weight when it was withdrawn. Multiple-baseline designs have also been used. Morganstern (1974) used a multiple-baseline-across-behaviors design in showing that a self-administered aversion procedure decreased consumption of different target foods only when specifically applied to each food in sequence. Similarly, Epstein et al. (1976) described the use of a multiple-baseline-across-subjects design in demonstrating the role of instructions in the regulation of eating in obese and nonobese children.

A third form of single-case methodology, as yet to be used systematically in the modification of obesity, is the changing criterion design (Hartmann & Hall, 1976). In this design, following a stable baseline period, the treatment method is applied in order to reduce weight to a designated level. When this target weight is reached, the criterion (target

weight) is lowered further. The criterion is progressively lowered until the ultimate goal of weight reduction is attained. A functional relationship between treatment and weight change is said to be demonstrated if behavior (weight loss) repeatedly matches the criterion as the criterion is changed. Kazdin (1975) has pointed out that this design is particularly well-suited to behaviors that have to be shaped to reach a final goal. Emphasizing as it does the slow but steady reduction of weight, the behavioral treatment of obesity clearly fits this description.

Single-case experimental designs are not without their limitations (see Bandura, 1976; Franks & Wilson, 1977; Hersen & Barlow, 1976). In general, single-subject demonstrations offer no information of the generality of the findings to other cases. Nor do they permit evaluations of the comparative efficacy of different treatment methods. There are also specific problems. Reversal designs are uninterpretable if the pretreatment baseline does not recover when the therapeutic technique is withdrawn. A successful reversal design demonstrates a causal relationship between treatment technique and target behavior but, by definition, excludes one investigation of maintenance of treatment-produced change. The latter is of major importance in obesity research (see below). Interpretive problems are encountered with multiple-baseline designs when behavior change generalizes across behaviors, settings, or subjects. The changing criterion design cannot rule out confounding sources of behavior change even if weight losses consistently match the changing criterion. The introduction of each treatment phase can always be associated with events extraneous to the specific treatment method.

However, weight reduction as a target behavior appears to be relatively free of some difficulties that often beset single-subject methodology in applied settings. For example, it is usually possible to obtain stable baselines of sufficient duration before intervening with treatment, a fundamental requirement of an interpretable single-case experimental design. Clear-cut treatment effects that are discriminably different from pretreatment (baseline) level are commonplace. Furthermore, unlike many other target behaviors, normative data

exist that allow judgments about what constitutes a clinically significant weight loss.

Between-Groups Design

The methodological considerations that govern the use of between-groups designs are described in detail elsewhere (Campbell & Stanley, 1966; Paul, 1969). Suffice it here to address some specific issues that pertain directly to the evaluation of the treatment of obesity.

The treatment package strategy. Much of the outcome research on obesity has followed the treatment package strategy (cf. Kazdin & Wilson, 1978). In this strategy multiple techniques are administered as part of a single therapy program that is compared to a no-treatment or attention-placebo control condition. Assuming the internal validity of the study, a significant difference between the treatment and control groups can be taken to indicate a causal relationship. The purpose of this strategy is to achieve maximal weight reduction. Accordingly, as Azrin (1977) pointed out, these treatment package programs should "include as many component procedures as seem necessary to obtain, ideally, a total treatment success" (p. 144). Exemplifying many behavioral evaluations of behavioral programs, the Penick et al. (1971) study used a multi-component behavioral approach that included "everything but the kitchen sink" (Stunkard, 1976, p. 219). If this treatment package proves effective in producing weight loss, then experimental analyses of its various components can be undertaken to elucidate the reasons for treatment success and thereby subsequently refine and enhance the efficiency and efficacy of that treatment approach.

Among the problems to avoid in using this research strategy is the necessity of ensuring that the treatment package is not so complex and wide ranging that it becomes difficult to identify and distinguish among the specific techniques within such a multifaceted program. Moreover, the total program must be distinguishable operationally and conceptually from alternative treatment or control procedures against which it is compared. It follows that it is essential to describe treatment packages in a clear, operational fashion in order to

permit the reader of the manuscript to replicate the treatment procedure. All too often cursory reference is made to "the standard behavioral self-control program" or the "Stuart treatment program" in the description of procedures used to treat obesity. Vague, nonspecific descriptions such as these complicate evaluation and seriously hinder replication. Ideally, the investigator might make available the detailed treatment program manual to readers interested in further information about the procedure.

Constructive and dismantling research strategies. Broad-spectrum behavioral treatment programs have been consistently shown to produce greater weight loss than alternative approaches in the short term. Since a treatment effect has been demonstrated, component analyses of the active ingredients of these programs are appropriate targets of research. Experimental analyses of the efficacy of specific techniques, both singly and in combination, are especially called for in view of certain findings. Several studies have demonstrated that individual component parts of the broader behavioral treatment package can produce weight losses equal or superior to those effected with the full program (e.g., Bellack, 1976; Green, in press; McReynolds & Paulsen, 1976; Romanczyk, Tracey, Wilson, & Thorpe, 1973; see further discussion of this issue in Franks & Wilson, 1977).

There are two fundamental research strategies for analyzing the component parts of multifaceted treatment packages. In the constructive treatment strategy (McFall & Marston, 1970), the effect of a single, narrowly circumscribed treatment component is established, and extra components are added sequentially to determine if they enhance treatment effects. The effective components are retained as the larger treatment program is constructed. Illustrating the constructive strategy, Romanczyk et al. (1973) compared the following treatment groups: (a) no treatment control (waiting list); (b) self-monitoring control (weight only); (c) self-monitoring control (weight and calorie intake); (d) self-monitoring and symbolic aversion; (e) self-monitoring, symbolic aversion, and relaxation; (f) self-monitoring, symbolic aversion, and relaxation and behavioral management (stimu-

lus control) instructions; and (g) self-monitoring, symbolic aversion, relaxation, behavioral management, and contingency contracting. This design enabled the investigators to assess the incremental value of including different treatment techniques in the overall treatment package.

In the dismantling strategy (Lang, 1969), specific components are systematically eliminated and the associated decrement in treatment effect is measured. The relative contribution of each component to the total treatment package can then be assessed.

Comparative treatment strategy. A detailed discussion of the conceptual and methodological issues involved in a comparative treatment outcome research is beyond the scope of the present article (but see Kazdin & Wilson, 1978). Only some of the more pressing concerns are mentioned here. Well-controlled comparative outcome research entails the comparison of clearly specified, operationally distinguishable methods. Vague descriptions of therapeutic interventions in global terms such as "the Stuart behavioral treatment program," "group psychotherapy," or "insight therapy" are unacceptable. The specific procedures embraced by these general labels need to be spelled out. Similar problems attach to the comparison of treatment methods with something termed *routine treatment*. As a standard for comparison, treatments labeled as routine vary enormously in nature, ranging from those that include several active treatment ingredients to those that are minimal control conditions.

Of major importance is the need to ensure that an evaluation of any given treatment approach represents an adequate test of that approach. Behavioral methods are often compared with treatments described as "psychotherapy." In most instances the psychotherapy condition is more accurately construed as an attention-placebo control group. Drawing conclusions about the superiority of behavioral methods over traditional psychotherapy on the basis of these studies is inappropriate. The Penick et al. (1971) comparative outcome study provides a relatively rare example of the comparison of a behavioral program with an alternative method that was adequately representative of traditional therapy for obes-

ity. Öst and Götestam's (1976) study in which a behavioral method was contrasted with pharmacotherapy is another instance of a legitimate comparative outcome evaluation.

Different treatments must be distinguishable on an a priori basis and in their implementation. If these procedural differences are blurred, the results become uninterpretable. A study might be designed to evaluate the effect of a specific behavioral method such as self-monitoring of daily caloric intake. If, however, subjects in the comparison group not intended to engage in such self-monitoring learn about this procedure and implement self-monitoring themselves, the independent variable will have been compromised. The probable outcome of no differences between groups will be uninformative. Bellack, Rozensky, and Schwartz (1974) compared two forms of self-monitoring in which subjects monitored their behavior either before or after they ate. The two groups were not significantly different from each other. However, it is unclear whether subjects in the premonitoring condition complied with this procedure. Green (in press) had external observers systematically rate obese subjects' adherence to treatment instructions and found that fewer subjects in a premonitoring condition adhered to instructions than subjects in a postmonitoring condition. Green's finding that this temporal factor in self-monitoring did not significantly influence weight loss is therefore more interpretable than Bellack et al.'s data. Treatment procedures cannot be properly evaluated unless they are implemented, a factor that has possibly contributed to the great variability in treatment outcome with behavioral techniques.

The identification of the effective components of obesity treatment programs is impaired by the failure to assess subjects' adherence to treatment methods independently of outcome. The intent of most behavioral programs, for example, has been to alter eating habits as a means of producing weight loss. Typically, the independent variables of studies (manipulation of eating habits) have been inferred, quite inappropriately, from treatment outcome. Several strategies exist for assessing subjects' adherence to the treatment program. Both Hagen (1974) and Wollersheim (1970) used an eating patterns ques-

tionnaire to assess habit change. They reported significant positive correlations between weight loss and questionnaire responses. However, a questionnaire measure administered only once at the end of treatment is probably the least satisfactory means of determining subjects' eating patterns. Using subjects' self-monitoring records of daily eating behavior during the 1st and 5th weeks of treatment, Jeffery et al. (1978) found that changes in eating patterns were unrelated to weight loss. Similarly, Bellack et al. (1974) found no relationship between subjects' self-ratings of adherence to treatment guidelines and weight loss. Brownell (in press) used a similar but more comprehensive approach by assessing subjects' daily self-reports of 38 different weight-related behaviors over the entire treatment phase. Correlations among these measures and weight loss were nonsignificant. Continuous assessment offers obvious advantages.

Brownell (in press) had subjects' spouses rate their eating patterns as a means of obtaining estimates of their accuracy. Similarly, both Green (in press) and Öst and Götestam (1976) trained observers to rate subjects' target behavior. The latter reported a significant correlation between habit change and weight loss. The use of external observers provides a reliability check of subjects' self-reports of behavior change. However, the investigator should be alert to the possibility that this procedure is reactive. Green, for example, found that the use of external observers was differentially reactive across different treatment methods. (See Nelson, 1977, for a discussion of the reliability and reactivity of self-monitoring.)

Control Groups for Treatment Evaluation

The function of control groups is to ensure the internal validity of the study by precluding the effects of weight change over time that are independent of treatment and the nonspecific influences of the treatment itself. As a rule the nature of the control group that is included will depend on the specific research strategy and the precise question that is the focus of investigation. However, some general comments are in order.

The most basic control group is the no-treatment condition. There are now sufficient data to show that weight does not change significantly as a function of the mere passage of time, the effects of repeated assessments, and other factors that the no-treatment condition is designed to control for. It is no longer a necessary control in a between-group study, and it is definitely not sufficient. Simply comparing a treatment method with a no-treatment control group is no longer acceptable. Nonspecific³ treatment control groups are necessary if causal relationships between specific therapeutic techniques and weight loss are to be demonstrated. Nonspecific influences can be controlled in one of two ways. In one, the study might include at least two treatment groups that differ from each other, as in the dismantling or comparative strategies, for example, but that incorporate the nonspecific influences of the therapeutic process. A difference between the groups would be attributed to a specific treatment effect rather than a nonspecific influence. Bellack (1976), for example, showed that a self-reinforcement method that included self-monitoring was more effective than self-monitoring alone in producing weight loss, a difference that was ascribed to self-reinforcement, since nonspecific factors were presumably equated across conditions.

The other means of controlling for nonspecific influences involves the inclusion of a pseudotherapy or attention-placebo control group, exemplified by Wollersheim's (1970) pioneering study. Contrary to the view that it has been shown to be relatively unimportant (Jeffrey, 1974), this form of control constitutes a necessary feature of a well-designed outcome study. One reason is that more recent research has shown that it is more difficult to control for nonspecific influences than was once supposed. Many attention-placebo control treatments have been found to be less credible to subjects than the active treatment (cf. Borkovec & Nau, 1972; Kazdin & Wilcoxon, 1976). In other words, independent assessment has indicated that not all attention-placebo control conditions are successful in equating nonspecific treatment influences, such as expectations of therapeutic improve-

ment. These findings are relevant to research on obesity. For example, relaxation training has been used as a control condition for nonspecific effects in some studies (cf. Hall, Hall, Hanson, & Borden, 1974; Hanson et al., 1976). Yet Ashby and Wilson (1977) found that obese subjects consistently rated the relaxation training component of their multifaceted behavioral program as being of little use. It is not unreasonable to infer that its use as a pseudotherapy control condition would be less credible than treatment involving other behavioral techniques. Studies should include independent evaluations of the efficacy of attention-placebo control conditions in controlling for nonspecific influences (e.g., Kingsley & Wilson, 1977).

Another reason for retaining nonspecific control groups in treatment outcome studies is the fact that they have resulted in significant weight loss in some cases. Kingsley and Wilson (1977), for example, demonstrated that a social pressure control group modeled after one of Wollersheim's (1970) control groups (which she had found to have little effect on weight) was effective in producing weight loss. The effects of this control condition were especially evident at long-term follow-up, an evaluation few outcome studies ever make. The state of the art is far too undeveloped to forego the necessity of incorporating stringent and verifiable nonspecific control groups in treatment outcome studies on obesity.

Simple inclusion of an attention-placebo control group is insufficient to control for nonspecific influences in certain situations. Specifically, it does not allow for evaluation of a treatment method unconfounded by expectations of behavior change and the general demand characteristics of the experimental or therapeutic setting. One solution to this problem is the use of countertherapeutic (Diament

³ The term *nonspecific* is misleading. The different treatment influences indiscriminately lumped together under this accommodating rubric are quite specific. It is more realistic to propose that although nonspecific factors remain to be specified, they are neither intrinsically unspecifiable nor qualitatively different from other variables involved in planned behavior change (cf. Wilson & Evans, 1976).

& Wilson, 1975; Steinmark & Borkovec, 1974) or nondemand (Abrams & Wilson, Note 1) instructions. For example, Diamant and Wilson (1975) evaluated the efficacy of covert sensitization on a taste-rating laboratory eating task. Both the covert sensitization and attention-placebo control groups participated in two taste-rating tasks, which they were led to believe were simply baseline measures preparatory to the "real" treatment. Although both groups in effect received treatment during the period between these two assessments, countertherapeutic demands were communicated that emphasized that they would not lose weight until the real treatment began. The two behavioral measures served as pretreatment and posttreatment measures of food consumption.

Miscellaneous Methodological Issues

Description of Subjects

Appropriate background and demographic data on subjects should be reported. A major problem in the obesity treatment literature is the absence of any reliable predictors of successful treatment outcome. Post hoc correlations among weight loss and diverse life history and personality variables have been unrevealing (Bellack, 1975; Stunkard & Mahoney, 1976). In general, the more overweight the subject, the more weight loss that can be expected. Accordingly, Jeffery et al. (1978) caution that initial weight should be controlled for in the analysis of other predictor variables. Rather than focusing on personal characteristics of obese clients, the search for predictor variables might be more profitable if attention is directed to *how* they respond to the initial treatment program (Jeffery et al., 1978) and to performance on specific treatment program-related tasks (Bellack, 1975). As with personality assessment in general, the emphasis should be on what the subject *does* in relation to specific controlling variables rather than what the subject is like (Mischel, 1968). Finally, the manner in which subjects are recruited for treatment studies should also be spelled out.

Subject attrition. High dropout rates in obesity treatment studies are not uncommon

(Stunkard & McLaren-Hume, 1959). Careful reporting of the precise number of subjects in each group that drop out of treatment is essential. An attempt might be made to ascertain the reasons for attrition and to assess the progress of dropout subjects throughout the treatment period whenever possible. Data collected from these subjects might be included in statistical analyses. Interpretation of treatment findings must be guided by the fact that subjects who drop out of treatment are almost certainly treatment failures in obesity (cf. Levitz & Stunkard, 1974) and other (cf. Kent, 1976; Sobell & Sobell, 1976) treatment outcome studies.

Description of Therapists

In its emphasis on specific treatment techniques, therapy outcome research on obesity has tended to gloss over the potential contribution to weight loss of the therapists who administer the treatment program. Although the therapists in behavioral weight reduction studies have ranged from undergraduates with no therapeutic experience (e.g., Jeffery, 1974) to graduate students in clinical psychology (e.g., Romanczyk et al., 1973) to experienced professionals (e.g., Levitz & Stunkard, 1974), this factor is often overlooked. It is not uncommon for manuscripts to provide virtually no information about therapists. Yet a clear statement of the therapists' sex, their degree status, and their therapeutic experience in general and familiarity with the treatment of obesity in particular is imperative. The importance of this information is underscored by the finding that professionally trained therapists were significantly more effective than nonprofessionals (leaders of lay self-help groups) in reducing client attrition during therapy and in effecting weight loss (Levitz & Stunkard, 1974). Similarly, Jeffery et al. (1978) reported that therapists who were more experienced in the conduct of obesity treatment groups achieved results significantly superior to those of less experienced therapists. The influence of therapist variables on treatment outcome is not surprising, and has been observed in the application of even highly structured behavioral techniques to clinical

disorders other than obesity (cf. Alexander, Barton, Schiavo, & Parsons, 1976; Johnston, Lancashire, Mathews, Munby, Shaw, & Gelder, 1976; Wilson & Evans, 1976).

The potential influence of therapist variables can be controlled and evaluated statistically by using more than one therapist in a design in which each therapist administers comparable amounts of therapy to all groups. If a single therapist administers all treatment conditions, it is impossible to disentangle the relative contributions of therapist versus treatment method. Another source of Therapist \times Treatment confounding occurs if different therapists separately administer different treatment methods to different groups (e.g., Penick et al., 1971). In the latter study, experienced professionals conducted the traditional psychotherapy treatment, whereas therapists who had had no experience in behavior therapy, and little therapeutic experience in general, administered the behavioral method. This strategy explicitly "stacks the deck" against the treatment administered by the naïve therapists. To the extent that this particular treatment proves to be superior, irrespective of therapists' expertise, it provides a powerful demonstration of the efficacy of that method. However, if the superiority is not clear-cut, or if the treatment administered by the inexperienced therapists proves to be less effective, then the results cannot be interpreted unequivocally. Thus Penick et al. (1971) found that behavior therapy produced greater weight losses, although the differences were not consistently statistically significant. Especially in view of Levitz and Stunkard's (1974) findings, it is entirely plausible that had the behavioral method been administered by experienced therapists, its superiority would have been more pronounced and its greater variability in outcome reduced.

Other Procedural Details

Descriptions of treatment programs should include the therapeutic rationale and treatment instructions, the scheduling of sessions, policies regarding absences, and arrangements for any make-up sessions. The time of year during which a study is conducted should also

be stated in view of reports that subjects tend to lose more weight in the spring and summer than in the fall and winter (cf. Ashby & Wilson, 1977; Jeffery et al., 1978; Mahoney & Mahoney, 1976).

Follow-up Evaluation

A major shortcoming in research on the treatment of obesity is the relative lack of long-term follow-up evaluations of therapeutic efficacy (cf. Wilson, in press). The significance of this striking deficiency is highlighted by the fact that obesity is a clinical disorder that has been characterized by consistently high relapse rates; that is, clients who lose weight during treatment usually regain it (cf. Stunkard, 1976; Stunkard & Mahoney, 1976). Yet although the importance of long-term follow-ups is consistently stressed, the overwhelming majority of manuscripts that are submitted for publication nonetheless fail to include appropriate follow-ups. It is as important to enquire into the reasons for this discrepancy as it is imperative that future treatment outcome research include long-term follow-ups.

Long-term follow-ups require the investment of considerable time and effort. Whether they can be completed successfully is often uncertain and unpredictable. Consider then the fact that a great deal of the research on obesity is conducted by graduate students and faculty in primarily academic settings. Clearly, long-term research—given these characteristics—is not the ideal stuff of which doctoral dissertations are made of. Under the current system of doctoral dissertation research training, most students would not have the time to conduct a long-term follow-up themselves; the realities of the situation appear to reward instead more manageable, more predictable, and time-limited studies. The importance of treatment outcome (especially long-term follow-up), as Azrin (1977) has suggested, becomes secondary. The contingencies governing the research behavior of faculty members seeking promotion and tenure in the increasingly competitive job market are not dissimilar. Outcome research emphasizing long-term follow-up represents something of a gamble; it is not optimal for

boosting publication frequencies and enhancing curricula vitae. In sum, if we are to reverse these contingencies—and, after all, behavior is at least partly a function of its consequences—we must encourage dissertation research that is relevant to treatment outcome. A student's participation in one facet (e.g., the long-term follow-up) of a broader research program might be viewed as a legitimate dissertation topic. This can—indeed *must*—occur without relaxing rigorous standards of scholarship and methodological sophistication. Our interpretation of research productivity of faculty must extend beyond the number of completed studies and incorporate an emphasis on the nature of the research.

Outcome evaluation of psychological treatments for obesity should distinguish among the initial treatment-produced weight loss, its generalization to the natural environment, and its maintenance over time (Bandura, 1969). Different factors might govern each of these processes, and it is now clear that generalization and maintenance will be ensured only to the degree that specific strategies toward that end are used (e.g., Kingsley & Wilson, 1977). The methodological strictures for the investigation and evaluation of treatment apply with equal force to maintenance or the follow-up phase of the study. All procedures followed should be explicitly described. Weight measures should be taken directly rather than relying on subjects' self-reports over the telephone or via mail. If different maintenance strategies are being compared, it is essential to ensure that they are actually implemented and that they are conceptually and operationally distinct.

In some instances subjects seek additional or alternative sources of treatment during the follow-up period. This creates problems of interpretation (cf. Kazdin & Wilson, 1978) but cannot be avoided. It would be both futile and unethical to attempt to dissuade subjects from seeking extra assistance for their problem. However, the nature and extent of these other therapeutic experiences should be assessed and reported.

Attrition Rates

Dropouts are more common during follow-up than the initial treatment phase and just as damaging to the interpretation of results. External validity is jeopardized, since attrition reduces generalizability; internal validity is compromised when there is differential attrition across treatment groups. Accordingly, every effort must be made to minimize attrition rates. Several procedures for accomplishing this crucial goal may be mentioned briefly (but see more detailed discussions of this issue in Hagen, Foreyt, & Durham, 1976; Sobell & Sobell, 1976).

1. Maintenance procedures and long-term follow-up should be an integral part of the design of a treatment outcome study and should be presented to subjects as such. In committing themselves to the treatment program, subjects also explicitly commit themselves to the follow-up. It is *not* something to be tacked on following treatment almost as an afterthought.

2. Investigators might remain in frequent contact with subjects. Regular phone calls or contact via the mail are recommended. Related to frequency of contact is the nature of that contact. Personal contact that represents an extension of the initial treatment phase is indicated. Since this continuing contact could well be reactive, that is, function as a type of maintenance strategy in its own right (Sobell & Sobell, 1976), precise procedural description is necessary.

3. A refundable deposit that subjects forego if they miss too many sessions or dropout significantly reduces subject attrition (e.g., Hagen et al., 1976).

Christensen (1976) has argued that current follow-up methods might provide weight measures that are unrepresentative of subjects' eating habits. Specifically, subjects might resort to drastic short-term means (e.g., fasting or diuretics) of reducing weight immediately prior to a follow-up weigh-in evaluation (cf. Mann, 1972). Christensen suggested that fixed follow-up dates be replaced by randomly scheduled weigh-ins. However, some subjects might object to this method. In any event, frequent contact during follow-up that stresses the importance of the personal rela-

tionship between subject and investigator would provide a detailed, representative assessment of subjects' eating habits and weight patterns.

Smoking-Cessation Research

Richard M. McFall
University of Wisconsin—Madison

Methodological problems associated with treatment research on cigarette smoking are explored, and possible solutions are discussed. The main problems considered are the selection and retention of subjects, the measurement of smoking, the design of treatment studies, and the interpretation and generalizability of experimental results.

The Surgeon General's Report (U.S. Public Health Service, 1964) on the health hazards of tobacco stimulated a wave of smoking research that has persisted into the present with little sign of abating. In fact, there has been so much published theory and research on smoking that it has spawned a secondary publishing enterprise consisting of periodic literature reviews (e.g., Bernstein, 1969; Lichtenstein & Danaher, 1976), scholarly books and conference reports (e.g., Borgatta & Evans, 1968; Hunt, 1970), and a monthly bibliographic bulletin (*Smoking and Health Bulletin*, published by the National Clearinghouse for Smoking and Health, Atlanta, Georgia).

Psychological research on smoking generally falls into one of four categories: studies of the causes of smoking, studies of its effects, studies of its prevention, and studies of various treatment approaches. Thus far the greatest share of attention seems to have been devoted to the last category, that is, to the search for effective methods of helping cigarette smokers reduce or eliminate their smoking behavior.

Despite the continuing interest in smoking-cessation research, investigators have shown surprisingly little awareness of the special methodological problems inherent in such research, or in the ways to avoid or overcome such problems. Methodological articles (e.g., Bernstein, 1969) seem to have been ignored

by some investigators. The present article is an attempt to draw attention, once again, to the critical methodological issues. In preparing the article, I have drawn illustrative material both from published manuscripts and from manuscripts that were submitted for publication but were found unacceptable. Since the purpose of the article is to promote better future research, rather than to criticize previous investigations, the sources of most examples will not be referenced.

Subject Issues: Problems of Generalizability

Who are the subjects? Smoking research typically is not conducted with a randomly selected sample of subjects from the entire population of smokers.¹ Similarly, smoking-cessation studies typically do not draw their subjects randomly from among all persons who may wish to quit smoking. Rather, the subjects in smoking studies are nearly always volunteers or recruits, whose relation to the parent populations of smokers or aspiring quitters is virtually impossible to determine. This fact immediately limits the generalizations that can be drawn from the results of specific smoking studies. For example, when volunteer subjects are used to study the personality correlates of smoking, one cannot assume that the findings are relevant to all

Requests for reprints should be sent to Richard M. McFall, Department of Psychology, W. J. Brogden Psychology Building, University of Wisconsin, 1202 West Johnson Street, Madison, Wisconsin 53706.

¹ Of course, the use of actual smokers as subjects in smoking-cessation studies allows greater freedom to generalize about the results than if analogue subjects had been used, as is the case in some other areas of behavior modification research.

smokers; it is possible that the findings may be more a function of the subjects' willingness to volunteer than their smoking habits. Similarly, if a smoking-cessation program either succeeds or fails with a particular sample of volunteers, there is no guarantee that the same effect would be achieved with smokers who chose—for whatever reason—not to volunteer. In fact, one might argue that the volunteer subjects in smoking-cessation programs are not representative of smokers in general.

Perhaps the typical volunteer is a member of a subgroup of smokers who are seeking an externally imposed, somewhat magical, solution to their problem. Furthermore, as the more promising candidates from among this subgroup manage to quit smoking, the remaining subjects may represent a distilled, hard-core group of treatment-resistant smokers. Only a small percentage of the volunteer subjects in most smoking-cessation studies manage to quit smoking and to remain abstinent for at least 6 months. Seldom do 20% achieve this measure of success! Based on such results, some investigators have concluded, rather pessimistically, that smoking-cessation techniques generally are not effective. It is interesting to note, however, that in the meantime many individuals seem to have given up smoking on their own—without volunteering as subjects in formal treatment programs. Thus, over the course of numerous smoking-cessation studies, the characteristics of the volunteer subgroup may be changing.

As if the inherent limitations of working with nonrandom samples were not enough, some investigators further limit the generality of their results by failing to report in detail (a) how they recruited their subjects and (b) the essential characteristics of their resulting sample. It would be valuable if investigators reported whether volunteer subjects were recruited from introductory psychology classes, by newspaper ads, or through referrals from physicians; it also would help to know specifically what the subjects were told that enticed them to volunteer. At the very least, investigators should always provide descriptive statistics on their sample's age, sexual composition, occupational and educational status, living arrangements, cur-

rent smoking behavior, and smoking history. The smoking history should include information concerning the pattern and form of tobacco consumption over the years, the chronicity of the habit, the history of any prior attempts to quit, and any significant health problems.

Another important question about the subjects in treatment studies is, what are their personal goals? So-called volunteers in smoking programs actually may be responding to cultural, social, medical, or family pressures; these subjects may be very different from those who volunteer without such coercive pressures. Even among genuine volunteers, however, there may be important differences in personal goals: Some may be committed to achieving total abstinence, whereas others may be satisfied with a significant reduction in their smoking. Few smoking studies have asked subjects beforehand to indicate their reasons for volunteering or to state their personal treatment objective.

Subject mortality. The problem of "subject mortality" (see Campbell & Stanley, 1963) is one of the biggest methodological problems, or sources of invalidity, in smoking-cessation research. If subjects are randomly assigned to different treatment conditions but some subjects drop out of the experiment prematurely, this loss seriously undercuts the investigator's ability to interpret and generalize from the experimental results. There is no way to rule out the possibility that the subject loss has been nonrandom, thereby rendering the treatment groups no longer comparable. Asking subjects why they dropped out of the study is no remedy; even when subjects give reasons that seem unrelated to the experiment, these explanations may be little more than polite excuses or rationalizations. The fact that equal numbers of subjects may have dropped out of the different treatment groups does not mean that the mortality problem has been avoided; it may be that different kinds of subjects dropped out of the different groups, thus making them no longer comparable in composition, although they remain comparable in size. Replacing dropouts with new subjects does not solve the problem either; the replacement may be very different from the original sub-

ject, thus altering the group composition. And there simply are no acceptable post hoc methods for statistically correcting for subject mortality by artificially matching or equating groups. The only valid solution is to retain all original subjects.

Unfortunately, volunteers for smoking-cessation programs are notoriously unfaithful subjects. Without using some kind of special inducement to stay in a study or constraint against dropping out, it has been virtually impossible to retain an adequate proportion of the original sample in most smoking studies.

One fairly effective method of inducing subject fidelity has been to require an "earnest deposit" before admitting a subject to a smoking-cessation program. For example, some experimenters have collected \$20 or \$25 from each subject at the time of admission and have promised to return the full amount at the end of the study, contingent on the subject's faithful participation. The deposit money was to be refunded regardless of the subject's treatment outcome, so long as the subject attended treatment sessions and provided the requested smoking data. Other investigators have used variations of this method. In one variation, the smoker forfeits a prorated portion of the deposit for each failure to attend or provide data.

In addition to using monetary incentives, the concerned investigator will want to do everything *within reason* to assure that subjects do not drop out. There is a danger, however, of going overboard in an effort to control subject mortality. For example, if an experimenter were to call each subject before every treatment session, provide transportation to and from sessions, send thank you notes, and serve hot cocoa and cookies, subject mortality might be reduced, but the generality of the experimental results would also be limited to treatments that included the elements of phone calls, transportation, thank you notes, and refreshments. Since such procedural elements are confounded with the treatment, they must be considered an integral part of the treatment. Thus, when designing methods to control the drop-out problem, investigators should seek methods that can be used reasonably by therapists operating in other contexts.

Measurement Issues: Problems of Reliability and Validity

What is "smoking"? If the objective in smoking-cessation research is to reduce or eliminate "smoking behavior," then it is essential to define this target behavior precisely. If we cannot define it precisely, we cannot measure it reliably, and this means that we cannot possibly determine whether our interventions have had any effect on it.

Specifying the target behavior in measurable terms is not as easy as it may seem. What is the best unit of measure for smoking? For example, should we count the packs consumed, the cigarettes consumed, the puffs taken, the volume of smoke inhaled, or the amount of nicotine and tar ingested? Should we assess these monthly, weekly, daily, hourly, or by the minute? Should we take into consideration the various stimulus situations in which the behavior occurs?

The most common measurement unit is the number of cigarettes consumed per day—with no systematic classification of smoking situations. But there is nothing sacred about this particular unit; in fact, it ignores a number of potentially important variables, such as the number of puffs taken, the amount of smoke inhaled, or, for that matter, the fact that certain brands of cigarette are significantly longer than others. What if a subject lights a cigarette, smokes it halfway, extinguishes it, and relights it later—does that count as one or two? Despite its limitations, investigators should consider using this common unit of measurement in future studies—perhaps along with other units—simply because it provides a standard basis for cross-study comparisons. Whatever units are chosen, they must be specified in sufficient detail to permit other investigators to use precisely the same unit.

What method of measurement is best? Once the investigator has decided on a measurement unit, for example, counting the number of cigarettes consumed per day, then it is necessary to devise a suitable method of actually gathering the desired data. This practical requirement is another major source of difficulty in smoking research. The following is a partial list of measurement options avail-

able to the investigator, along with a brief discussion of possible advantages and disadvantages of each.

1. Laboratory methods. The most accurate method of measuring actual smoking behavior is to observe it under controlled conditions, such as in the laboratory. To achieve accuracy and control, however, the investigator inevitably sacrifices representativeness. That is, smoking behavior observed in the laboratory may bear little resemblance to unobserved, nonlaboratory smoking behavior. The appropriateness of using lab measures depends entirely on the specific experimental question. For example, if one were assessing the relationship between anxiety and smoking, it would be appropriate to begin doing so in the lab by systematically manipulating levels of stress while measuring the smoking behavior. However, if one were interested in the therapeutic value of a particular intervention, then changes in laboratory behavior would not be regarded as meaningful or persuasive evidence of therapeutic change. Smoking-cessation studies may include laboratory measures as part of a larger group of dependent measures, but there remains the problem of devising suitable extralaboratory criterion measures.

2. Self-report methods. This is the most commonly used assessment method in smoking studies. Subjects are enlisted as collaborators in the data-collection process; they are asked to monitor, record, and report on their own smoking behavior. Of course, the advantage of this method is that no one is in a better position to observe a person's smoking behavior—across all situations and at all times—than that person herself/himself. One disadvantage is that the person's self-reported data may be biased, inaccurate, or falsified, and thus there remains the need for a suitable independent measure of the subject's smoking behavior. Another possible disadvantage of self-report measures is that they sometimes can be reactive; that is, when subjects self-monitor their behavior, this may significantly affect the behavior being monitored in some manner (McFall, 1970). For example, it is common for subjects in smoking-cessation programs who are asked to self-monitor their smoking frequency during a

baseline period to report that the monitoring makes it difficult for them to continue smoking "normally." Nevertheless, because subjects do have unique access to their own behavior, it seems that the advantages of the self-report method usually outweigh its disadvantages—at least in smoking-cessation research—and that it will continue to be the principal data-collection method in such research. The problems with the method simply will have to be controlled or minimized as much as possible (e.g., see Nelson, 1977, for discussion of self-monitoring effects and their control).

3. Unobtrusive naturalistic measurement. Webb, Campbell, Schwartz, and Sechrest (1966) have suggested a variety of approaches that investigators might use in their effort to obtain useful naturalistic data without being so obtrusive as to contaminate the data. Translating their general suggestions into assessment methods for smoking behavior will require creativity and inventiveness, but one illustrative possibility is presented here to help stimulate the reader's own imagination:

Smoking ordinarily results in the accumulation of residual evidence in the form of cigarette butts. By monitoring a sample of the likely deposit sites of butts—for example, ashtrays in the office, home, or auto—an investigator might get a reasonably good picture of within-subject changes in smoking patterns over time. The resulting data should provide an indirect check on the accuracy of a subject's self-report.

There are at least three problems with unobtrusive naturalistic methods. First, there are ethical and legal problems with poking around in another person's personal space, such as their auto, home, or office, without their informed consent; but to obtain full consent would surely do away with the unobtrusiveness of the measurement. Second, the availability of naturalistic smoking data will vary from subject to subject, depending on the particular environmental settings that each subject regularly frequents; thus, the samples obtained for different subjects may not be sufficiently comparable to permit an analysis of group data. Third, the collection of unobtrusive naturalistic data may be prohibitively difficult or expensive.

4. Collaborator reports. If the subject's self-reports are suspect and if the investigator cannot arrange to observe firsthand the subject's naturalistic smoking behavior, then a compromise solution may be possible. Perhaps a third party—someone living or working closely with the subject—could be enlisted as an observer of the subject's smoking behavior. This assessment method has been used with increasing frequency in recent years. Investigators typically have asked subjects to provide names of persons who would be in a position to observe their smoking and who could be contacted periodically for reports.

One problem with relying on such collaborator reports is that the persons providing the data ordinarily are close friends of the subjects and thus are not necessarily any more objective reporters than the subjects themselves. It has not been uncommon, for example, for subject and collaborator reports to be extraordinarily highly correlated (e.g., over .95). Such agreement cannot be automatically accepted as evidence that the subjects and collaborators have provided valid data; the high correlation may reflect little more than collusion between the subjects and collaborators. Unfortunately, there is no simple method of assessing the validity of collaborator-reported data, which means that this measurement method cannot stand alone as a validity check on subjects' self-reports.²

5. Correlates of smoking behavior. For years, investigators have searched for a reliable correlate of smoking behavior that they could use as a sensitive indirect measure in their smoking studies. Nicotinic acid stains on the fingers, respiratory flow volume, sputum samples, and blood assays are among the various measures that have been considered at various times with only limited success. Recently, however, a promising physiological correlate of smoking behavior—carbon monoxide levels in samples of expired air—has been identified and used successfully in smoking studies (Danaher, Lichtenstein, & Sullivan, in press; Lando, 1975). Brockway (in press) has reported that thiocyanate may prove to be yet another objective measure of cigarette smoking. More work along these lines seems as though it might be helpful.

In summary, no single measure of smoking

behavior is adequate. Until the absolute or ultimate measure has been discovered, investigators must rely on a network of measures, each of which can serve to cover the weaknesses or blind spots of the others. In any event, a more convincing argument for validity can be made when there is concurrence among several independently derived measures.

Assessing change. Smoking-cessation studies typically are composed of four assessment periods: (a) a baseline period, during which subjects' pretreatment smoking behavior is recorded; (b) a treatment period, which can be broken down into several subperiods corresponding to different phases of treatment or to units of time; (c) the end of treatment; and (d) a follow-up period, ideally covering a minimum of 6 months to 1 year. By assessing changes in smoking behavior over these periods, it is possible to evaluate the effects of different interventions. However, to the extent that any of the assessment periods are not adequately designed and controlled, the meaningfulness of the results will be seriously limited. Some of the most common design problems are discussed below.

The essential requirement of the baseline period is that it provide a solid anchor against which to weigh the magnitude and significance of changes in any subsequent periods. Thus, the most serious mistake that investigators can make during the baseline period is to fail to assure that their measure of pretreatment smoking behavior has stabilized before they initiate the treatment period. This flaw is not always apparent from post hoc inspection of the published data. It has become common practice to report only one data point—usually the mean smoking frequency—for the entire baseline period; this practice is unfortunate. An absolute minimum of three data points is necessary if one wants to estimate the stability of baseline behavior. A single data point may obscure underlying trends in the data that might sub-

² It may be useful to distinguish between differences in accuracy as a function of the type of data being collected. It probably would be easier for a collaborator to report accurately on a subject's abstinence than on the subject's smoking rate.

stantially affect how one would interpret the experimental results.

Another common methodological problem encountered in the baseline period is that experimental groups sometimes are found to differ prior to treatment.¹ This difference need not be statistically significant to be considered serious. And when initial group differences do exist, there is little that can be done to correct the problem once the experiment has been carried out. Thus, before proceeding to introduce any differential treatments, investigators routinely should examine their baseline data to be certain that the groups are comparable. If the groups are not comparable, they still can be reconstituted at that point and the experiment can be salvaged. (After randomly reassigning subjects to treatment conditions, the baseline period must be repeated, of course.)

The treatment period obviously is devoted to the introduction of the experimental intervention. The introduction of the independent variable, however, does not mean that the dependent variable can be ignored during this period. On the contrary, it is essential to an analysis and interpretation of any experimental effects that the dependent variable be carefully assessed during treatment as well as before and after. Only in this way will it be possible to evaluate closely how the treatment exerted its effect on smoking. For example, in a smoking treatment designed to produce a gradual withdrawal from smoking, one would want to have several subjects actually follow the expected gradual decrease. In other words, assessments conducted during the treatment period permit an interim analysis of the treatment process itself, whereby adjustments can be made before and after treatment period on a basis of (1) individual and (2) group differences.

Lehmann (1971) has recently argued that there is too often an ad hoc analysis of the treatment process when the experimental researcher fails to produce a significant outcome difference. Subject to the foregoing, it is a sensible response that argument of design is better. That is, more effective treatments need to be designed for publication by the kind analysis of significant within-treatment group differences that were intro-

lated to meaningful outcome variables. Such analyses are potentially valuable, however, to the individual investigator who needs to understand what went wrong or what might account for the failure to obtain significant outcome differences. Without such process information, it is difficult to rise above one's failures and to design better treatments.

The bottom line question in smoking cessation research is the outcome question: Did the treatment work? This must be answered within two outcome time frames: immediate and long term. The end-of-treatment assessment provides an immediate measure of treatment effects; it also marks the transition from treatment to follow-up periods. When compared to the baseline measure, it provides a summary assessment of change over the treatment period. It also represents a benchmark against which to compare subsequent assessments and to evaluate the long-term maintenance of changes. The end-of-treatment assessment must contain the same measures used in the baseline period and in the follow-up period; otherwise, a valid assessment of change is not possible. That is, subtle variations in measurement procedures from period to period may make meaningful comparisons difficult or impossible. For instance, it would be questionable practice to assess pretreatment to posttreatment change by using self-monitored data at the baseline period and subjective estimates of smoking frequency at the posttreatment period.

A well-designed follow-up period is the one question of a valid therapy outcome study. Unfortunately, the follow-up period seems to be one of the weakest links in most smoking cessation studies. It seems such a waste of resources for an investigator to be meticulous about carrying out the baseline treatment and posttreatment periods, only to be lax about the follow-up.

Subject mortality is the most common follow-up problem in smoking cessation studies. It is a problem that seems to be repeatedly related to the length of the follow-up period. The longer the period (a virtue), the more likely that subjects will be lost (a fault). The unfortunate implications of subject mortality already have been discussed. The solutions are not as easily outlined. Perhaps the single

important factor in eliminating the problem of the persistence and determination of the investigator in pursuing the study of each every subject. When an investigator reports that some subjects "could not be located for the follow-up assessment, one cannot help but wonder to what lengths the investigator actually went to locate the missing subjects."

The follow-up measure of smoking should be comparable to the one used in the baseline and end-of-treatment assessments. It has not been uncommon for investigators to rely on unconfirmed global self-reports of smoking frequency, obtained from subjects via either telephone conversations or preaddressed postcards as their primary follow-up measure. Such a casual approach to assessment would be unacceptable in the other experimental periods. It is equally unacceptable in the experimental period from which ultimate conclusions concerning the treatment outcomes are drawn.

As has been pointed out elsewhere (McFall & Hammen, 1971), virtually any plausible smoking-cessation treatment that one can imagine is capable of producing a significant temporary reduction in smoking behavior. However, few treatments have managed to produce sustained reductions exceeding those obtained by placebo treatments or minimal-treatment control conditions. An assessment of changes in smoking behavior across the experimental periods, therefore, is bound to yield a statistically significant main effect in virtually all studies, but is unlikely to yield significant between-treatment differences. Only the discovery of significant treatment differences is remarkable enough, at this stage in the history of smoking cessation research, to warrant publication or general dissemination of the results. There are two exceptions to this rule. (One is when an established intervention that had come to be expected to yield significant results fails to do so, another is when a truly novel treatment approach, derived from a reasonably prominent theory, is found to have an effect. In general, the publication value or newsworthiness of a finding is directly related to its unexpectedness.

Interpretation of results. If the results of the smoking-cessation experiments are to be compared and integrated, they must be

presented in a manner that permits cross-study comparisons. In the past, many investigators have tended to report their results in unconventional ways, which has frustrated efforts to make such comparisons. A standardized format for data presentation would greatly improve this situation. (Of course, the use of a standard format would not prevent authors from presenting their data in other formats, in addition, when it served their special purposes.)

Convention suggests that the standard format might include as a minimum (a) period-by-period changes in smoking frequency, expressed in terms of a percentage of the baseline mean, and (b) the percentage of subjects within groups achieving total abstinence (and other lesser target levels, if appropriate). Both summary statistics should take into account all subjects who entered treatment, not just those who completed treatment.

Treatment Issues: Problems of Relevance and Replicability

Research strategies. Smoking cessation research can be characterized as "a problem in search of a cure." That is, investigators typically have been concerned with testing the effects of one or more experimental treatments on the smoking behavior of their subjects; the aim has been to find an effective method for helping people kick the smoking habit. The specific research strategy used in any given study usually falls into one of the following four categories.

1. **House races.** The most common strategy has been to line up several promising treatment methods along with a control treatment, and to give them all a run for the money under common conditions, with randomly assigned subjects from the same population. The judged by the same outcome measures. The competing treatments need not be related to one another in any systematic way other than their common goal. At the conclusion of the house race, the results are interpreted in a straightforward manner, namely in terms of the relative effectiveness of the various treat-

The new investigator might anticipate the over-take problem at the outset by obtaining names and addresses of persons who would know the whereabouts of each subject at follow-up.

ments included in that particular comparison. The results have little theoretical significance; they reveal little about the reasons why things turned out as they did.

2. *Dismantling strategy.* Once an effective change technique has been found, it can be examined more closely in subsequent studies in which it is systematically dismantled to see how its various components contributed to the overall treatment effect. This strategy has been used relatively infrequently in smoking-cessation research, to date, because few treatments have proved themselves sufficiently promising to warrant such an internal analysis. One exception has been the "rapid smoking with warm, smoky air" technique reported by Lichtenstein and his colleagues (Schmahl, Lichtenstein, & Harris, 1972). The experience of these investigators, however, illustrates one of the potential frustrations of the dismantling strategy. When Lichtenstein, Harris, Birchler, Wahl, and Schmahl (1973) compared the relative effectiveness of the rapid-smoking component, the warm, smoky air component, and the combined components, they found that all three treatment conditions were comparably effective. That is, each component alone yielded the same level of effect as the two components combined. In this instance, the dismantling strategy failed to reveal very much about the mechanics of the treatment effects.

3. *Constructive strategy.* This approach, like the preceding one, assumes that a fairly effective intervention has been found. Using the established intervention as a solid treatment base and as a comparison condition, additional components are systematically added in an attempt to increase the consistency or magnitude of the overall effect. The primary aim of this pragmatic strategy is to build a maximally effective treatment. To use this strategy, it is not necessary to understand precisely how the various components function or interact; this approach emphasizes outcome over process. However, without some guiding theory, the selection of components to be added to the treatment package is likely to be haphazard and inefficient.

4. *Theoretical research.* The most advanced research approach would be one based on a theory of smoking behavior and would be designed to test hypotheses derived from that

theory. Ideally, such research would lead to the most substantial advances, both scientific and technological. Unfortunately, there are few promising theories available at present to guide or stimulate such high-level research in the area of smoking behavior. History has shown that good theory is unlikely to come from the grand speculations of armchair thinkers; it usually arises out of attempts to integrate and organize empirical observations. Thus, there is reason to hope that smoking research eventually will manage to bootstrap its way from horse race studies, through dismantling and constructive studies, to theoretically grounded research.

An alternative research strategy deserves mentioning. It is a relatively unexplored, more indirect approach to the task of discovering an effective treatment. Investigators might learn a great deal if they took time out from their treatment studies to look closely at the various methods that have been successfully used by the multitude of former smokers who have quit on their own. There may be effective "folk methods" that could teach us a great deal about smoking behavior and its treatment.

Interpreting the results. An investigator's choice of a research strategy has important implications for the subsequent interpretation of the research results. There seems to be an inherent antagonism between the two research objectives of relevance and replicability. On the one hand, designs that foster relevance, such as those used in clinical trials or in horse race studies, tend to be so non-specific and uncontrolled that they cannot be easily replicated. On the other hand, designs that foster replicability tend to be so tightly controlled and specific that they have limited immediate relevance to the clinical treatment setting.

At the former extreme would be a clinical study in which clients are treated over an extended period by a combination of procedures that can be described in only the most general terms. The clients who quit smoking represent genuine successes, but it would be virtually impossible to specify and reproduce all of the factors that contributed to their quitting.

At the opposite extreme would be laboratory analogue experiments in which unmoti-

rated subjects are led to believe that their smoking behavior is being studied for reasons unrelated to smoking reduction, in which they are exposed to a brief experimental manipulation, and in which changes in within-lab smoking behavior are the dependent variables. The results of such an analogue study cannot reasonably be interpreted as bearing directly on the clinical treatment of smoking. Campbell and Stanley (1963) have presented with great eloquence and clarity a detailed list of factors that must be experimentally controlled before an investigator can hope to interpret the results of any experimental or quasi-experimental study. A summary of their presentation is beyond the scope of this article. However, if there are any readers who have never read the Campbell and Stanley monograph, it really should be considered required reading before attempting to design any smoking studies. In fact, readers who have read it but have not reviewed it recently are strongly urged to do so.

Generally, it is helpful to remind ourselves that the aim of experimental research is the elimination of plausible rival alternative hypotheses. Viewed from this perspective, experiments never prove that particular hypothetical conceptions are true; rather, at best, a hypothesis gains in stature to the extent that it manages to survive rigorous experiments that are designed to disconfirm it, whereas competing hypotheses are disconfirmed by such experiments. In smoking-cessation research, for example, four of the most common competing hypotheses are:

1. Perhaps no systematic change even occurs.
2. If change does occur, perhaps the experimental treatment does not produce a greater change than do competing treatments.
3. If the experimental treatment produces the greatest change, perhaps the change is not durable.
4. If the experimental treatment is associated with the greatest and most durable changes, perhaps such changes can be explained more simply by uncontrolled factors aside from those that are part of the experimental treatment per se.

Even after these basic "null" hypotheses and "nonspecific factors" hypotheses have

been eliminated, and a treatment has been established as unquestionably effective, there remains the task of sorting through all of the various possible explanations for the mechanics of how the treatment works. Again, this is a process of eliminating alternatives until only a few are left standing. (The ideal of having only *one* alternative remaining is seldom if ever achieved.)

The interpretation of experimental results must always be presented with reference to the particular rival hypotheses that either were discredited or failed to be disconfirmed. Since no single experiment is likely to pare the list of alternative rival hypotheses down to a single survivor, all prominent surviving competitors should be recognized in the discussion and interpretation of a particular study. Suggestions for future studies designed to test the survivors are always welcome.

Negative side effects. Recent events in the area of smoking-cessation research have helped to emphasize the need to be sensitive to possible unanticipated negative side effects of our experimental treatments. Lichtenstein's rapid smoking technique has been one of the few treatments to achieve reasonably convincing and consistent effects—for example, abstinence rates after 6 months of 57% or more (Lichtenstein et al., 1973). However, this treatment recently was found to pose a potentially dangerous health hazard itself, especially if applied to patients with impaired coronary circulation (Hauser, 1974; Miller, Schilling, Logan, & Johnson, 1977). Fortunately, the major proponents of the rapid-smoking technique have been sensitive to the dangers and have urged that medical precautions become a standard preliminary to administering the treatment (Lichtenstein & Glasgow, 1977). Proponents of other treatments should show a similar sensitivity to the possible risks or costs of their interventions.

Going public. Once an efficient, safe, and effective treatment for cigarette smoking has been established through well-controlled research, there remains the problem of translating such an experimental treatment into a valid procedure for widespread use with the general public. Campbell and Stanley's (1963) discussion of external validity issues explores this problem thoroughly; however, some investigators apparently need to be re-

mindful of some of the most critical issues. For example, a recently published self-help book purports to offer the consumer an experimentally validated method for kicking the smoking habit. Assuming that the particular method may have been shown to be effective when administered in a controlled setting to selected subjects by trained therapists is not a sufficient basis for "going public" with the method in the form of a popular self-help book. Before going public in this way, the authors should demonstrate empirically that the method is effective with subjects who buy the book and self-administer the treatment (see Glasgow & Rosen, 1978)!

Conclusion

The methodological vagaries and pitfalls of conducting smoking-cessation experiments have been outlined and discussed. Where possible, suggestions for improved research were also offered. Generally, the standards for good design in smoking research are not different from the standards for research in other clinical areas. The very nature of smoking behavior, however, poses certain difficulties in attempts to achieve those design standards. Specifically, measurement problems have been a chronic weakness in smoking studies.

Despite the extensive efforts of numerous investigators over many years, cigarette smoking continues to be a major health problem. An efficient, safe, effective treatment for smoking behavior remains an elusive goal, although progress toward this end seems to have been made in recent years. Hopefully, the present article will help hasten the day when the goal is realized and when it will be possible to help large numbers of smokers kick the habit.

Common Methodological Problems in Research on the Addictions

Peter E. Nathan and David Lansky
Rutgers—The State University

Among the common methodological problems in research on the addictions reviewed in this article are (a) selective, incomplete, or biased reviews of the body of prior research from which a study has arisen; (b) reliance on inadequate or incomplete diagnostic criteria in choosing subjects for study; (c) choice of inappropriate comparison groups for treatment outcome research; (d) use of inadequate alcoholic analogues when alcoholic subjects are unavailable; (e) failure to adequately account for treatment dropouts in analysis of treatment outcome data; (f) unwarranted choice of single-subject over group designs in addictions research and vice versa; (g) failure to ensure that comparably trained, equivalently committed therapists provide both experimental and control treatments in treatment outcome studies; (h) failure to ensure that patients in both experimental and control treatments receive treatments as therapist- and time-intensive; (i) failure to follow patients for adequate lengths of time posttreatment; (j) failure to provide for adequate, multidimensional treatment outcome measures tapping a full range of patient behavior; (k) failure to exercise restraint, scientific modesty, and criticality in reporting results of one's own research; and (l) failure to recognize important differences between statistical and clinical significance.

This article identifies common problems in research on the addictions. It also offers suggestions for remediating these methodological problems. The addictions considered in the article include alcoholism and the drug dependencies. Because the literature on alcoholism is much more extensive than that on drug addiction, most of the common errors reviewed are drawn from the alcoholism literature. Despite this focus, there is enough commonality between methods of research on alcoholism and drug dependence that criticism in one research area almost always has relevance to the other.

The first problems to be considered are those arising from inadequate, incomplete, or

biased reviews of relevant literatures. Next, methodological shortcomings of subject selection, research procedure, and data analysis are detailed. Consideration of problems in the presentation of results and their interpretation and discussion concludes the article.

Literature Review and Statement of the Problem

Although it might be considered gratuitous to begin this article by pointing out the impact that selective, incomplete, or biased reviews of research have on the impact of research findings, it is important, nonetheless, to recognize that the alcoholism researcher may be particularly liable to this temptation. Otherwise called "enlightened historical selectivity," this tendency comes easily to the addictions researcher who is forced to choose one position, from several, on such controversial matters as etiology (Sociocultural, genetic, metabolic/physiological, and behavioral views are foremost.) and treatment.

Preparation of this manuscript was facilitated by National Institute for Alcohol Abuse and Alcoholism Research Grant AA 00259 to the first author.

Requests for reprints should be sent to Peter E. Nathan, Department of Clinical Psychology, Graduate School of Applied and Professional Psychology, Busch Campus, P.O. Box 819, Rutgers—The State University, Piscataway, New Jersey 08854.

(Dynamic, behavioral, medical, and peer-group Alcoholics Anonymous treatments are available.) This breadth of available perspective has, in turn, been largely responsible for the proliferation and perpetuation of invalid "common truths" and unsubstantiated "old wives' tales" in this field.

Selective or biased reviews of the alcoholism literature have supported a variety of such "truths" through the years, including that alcoholism is a medical disorder (and that as a result, abstinence is the only appropriate treatment goal for alcoholics), that all alcoholics experience loss of control over their drinking, that "dry" alcoholics are the best therapists for other alcoholics, that alcoholics drink to reduce prevailing high levels of tension and anxiety, that alcoholics are oral-dependent individuals who have not come to terms with their needs for nurturance, and so on.

One area of alcoholism and drug addiction research—having to do with the etiology of alcohol and drug dependence—has been especially subject to the stultifying influence of selective biases on review and interpretation of research results. Since significant federal funding for alcoholism and drug research became available about a decade ago, unitary models of dependence have been largely disproven. Specifically, there do *not* appear to be characteristic personality patterns that differentiate drug abusers from nonabusers, there is clearly *not* a single route to alcohol or drug dependence, and alcoholics and non-alcoholics do *not* appear to metabolize ethanol in discernibly different ways at comparable levels of ingestion. Instead, the mechanism of dependence, the etiologic process, the personality structure of alcoholic and drug-dependent individuals, and their motivation for and response to treatment all depend on far more than intrapsychic or physiologic factors alone. To this end, the literature now supports a more sophisticated view, that of a complex individual system interacting with personal history and environmental factors to yield an addiction. Among the most clearly articulated of these new, more constructive points of view is the behavioral viewpoint on the addictions, well-stated by psychologists Miller and Eisler (1975):

Within a social-learning framework alcohol and drug abuse are viewed as socially acquired, learned behavior patterns maintained by numerous antecedent cues and consequent reinforcers that may be of a psychological, sociological, or physiological nature. Such factors as reduction in anxiety, increased social recognition and peer approval, enhanced ability to exhibit more varied, spontaneous social behavior, or the avoidance of physiological withdrawal symptoms may maintain substance abuse. (p. 5)

From another perspective, that of tongue-in-cheek, Mark Keller (1972), alcoholism's long-time Dean of Letters, says the following about unidimensional theories of alcoholism:

A splurge of reports, in the 1940's, of biochemical characteristics purporting to differentiate alcoholics from nonalcoholics stimulated me to review a voluminous related literature, implicating physical, social and psychological demarcators as well. The only conclusion I could derive, from the entirety of the reportage, took a form that became known, among colleagues, as Keller's Law: *The investigation of any trait in alcoholics will show that they have either more or less of it.* Accordingly, I then predicted that if sexadactly should be investigated, alcoholics will yield either more or fewer six-toed and six-fingered people than a control population. (p. 1147)

Subjects

Diagnostic criteria. The familiar problems that plague diagnostic decision makers called on to make diagnostic distinctions among psychiatric patients (Chapman & Chapman, 1977; Goldberg, 1968; Nathan, 1967) also confront the researcher who must select alcoholics from a general population and, as important, assure that the subjects chosen are representative of an identifiable portion of the universe of alcoholics. It might appear that choosing alcoholics must be easier than selecting schizophrenics or neurotics, because all alcoholics share a single stigma—they drink too much. But the task is made more difficult than it might seem by lack of consistency, in research reports, in detailing this hallmark of the disorder. For example, descriptions of alcoholics recently studied by psychologists range from "twenty subjects [who were] psychiatric patients with a primary diagnosis of alcoholism" (Levine & Zigler, 1976, p. 141), and "alcoholic Ss [subjects] [who] were volunteers from the patient population of the Alcoholism Treatment Program at the VA hospital" (O'Leary, Radford,

(Chaney, & Schau, 1977, p. 580) to

subjects [who] were three male veteran inpatient volunteers, ages 40, 50, and 55 years. They reported histories of chronic drinking of 15, 20, and 26 years, respectively. Each had experienced blackouts and delirium tremens as a result of drinking and had been hospitalized 9-20 times for alcohol-related problems. The subjects were each classified as binge drinkers consuming up to 140 ounces of beer and 40-70 ounces of liquor per day when drinking. Drinking episodes ranged from 5-30 days followed by a 10-day (on the average) period of sobriety. (Doleys, Caminero, Wallach, & Davidson, 1977, p. 207)

Leaving aside the question of which of these studies most carefully ensured that its subjects were in fact alcoholics, it is clear that only the latter article provides enough information to permit assessment of the extent to which the subjects studied were comparable to alcoholics studied elsewhere.

The greatest possible detail about drinking pattern must be conveyed in a research report. Above all, researchers—and their audience—must become unwilling to consider men and women as alcoholics simply because they received that diagnosis from someone somewhere at some time. Instead, hard signs of physical dependence, psychological dependence, and tolerance ought to be in evidence, along with indications that alcohol has been a problem in living and that problems in family relationships, vocational adjustment, and interpersonal relationships have followed from excessive alcohol consumption.

Although use of a broad range of assessment procedures is an essential aspect of alcohol and drug treatment research, the ultimate utility of these measures can only be gauged by reference to their respective reliability and validity estimates. It is, therefore, incumbent on the responsible researcher to assess and report the adequacy of these measures as applied to the subject population in question. Unfortunately, it is rare that the reliability and validity of assessment procedures are reported in alcohol and drug treatment studies.¹

It is also important that age, sex, and socioeconomic status, at least, be summarized for all subject populations. As we have already observed, alcoholism does not wipe out the effect on behavior of subject variables

such as demography, education, and social class.

Even more formidable assessment problems confront the drug researcher, since only very recently have attempts been made to measure quantity and frequency of drug ingestion (e.g., Mirin, Meyer, McNamee, & McDougle, 1976; Rawlins, Randall, Meyer, McNamee, & Mirin, 1976). As a consequence, diagnosis of drug dependence is from whatever signs of physical dependence are available, whereas differentiation among varieties of drug abusers must be confined to descriptive typologies (e.g., heroin addict, amphetamine addict, polydrug abuser, and so on). However, Carlin and Stauss (1977) recently explored the possibility of categorizing drug addicts along functional dimensions, including a streetwise/straight typology (e.g., legality of primary means of support, conventionality of dress and grooming, ability to buy drugs from street drug dealers, etc.) and a self-medication/recreational drug-use typology. The major point of their article is that use of these descriptors, in conjunction with the more common descriptive typology, provides more information about subjects than the descriptive typology alone.

Control and comparison groups. Another common subject selection problem is choice of comparison groups when one wishes to contrast alcohol or drug abusers with nonabusers. If subjects are inpatients, must the comparison group also be hospitalized? And if it is, should it be composed of hospitalized psychiatric patients, because, presumably, alcoholics and drug abusers are often victims of psychiatric disorder as well? By the same token, if subjects are outpatients, can comparison subjects be chosen from any non-drug-abusing group or must they be psychiatric outpatients? In the same vein, how necessary is it to match experimental and control groups by age, sex, socioeconomic status (SES), level of education, and treatment motivation (if the latter is relevant to the study)? Our view

¹ For detailed information on unobtrusive approaches to the assessment of alcoholism and its concomitants, the reader can consult Briddell and Nathan (1976), Miller (1976) and Nathan and Briddell (1977).

of this complex matter is that alcoholics or drug addicts whose addictions are accompanied by concurrent psychiatric disorder must be compared to age-, sex-, and SES-matched nonaddicted individuals whose psychiatric diagnoses approximate those of the alcoholics. We do not assume, of course, that all drug-dependent individuals—or even most of them—are psychiatrically disordered just because they abuse drugs or alcohol.

Though an obvious and well-accepted control procedure, it is probably worth noting here, in passing, that groups of patients to be compared on the basis of treatment outcome must have been chosen from the same patient population to begin with, then assigned to treatment groups in a way guaranteed to ensure comparability. Of equal importance, in this context, is selection of a proper comparison treatment for alcoholics or drug abusers undergoing a nonstandard treatment whose efficacy is being assessed. In this regard, it is probably worth noting that "no treatment" or waiting list controls may be unethical when one is dealing with severely disabled addict populations. As important, they may also be unfeasible, since alternative treatment sources are often freely available to the motivated alcoholic or drug abuser. Most important, one must ensure that the control treatment that matched patients do receive is as active, long lasting, and time intensive as the new treatment being evaluated. This important issue is discussed in greater detail later.

A related control issue, in this context, is the treatment motivation of experimental and control subjects of comparative treatment studies. Failure to assess subjects' treatment motivation in treatment outcome studies involving small numbers of subjects, a common failing, prevents one from knowing whether apparent differences in treatment efficacy, if found, reflect real differences in the power of one treatment to effect changes in behavior or whether that treatment group simply included individuals who were more highly treatment motivated. Researchers fail to undertake this necessary assessment because doing so inevitably reduces the size of the pool of potential subjects and because the assessment is really not so simple. Above all, subjects may not tell the truth about their

treatment motivation, especially when financial, vocational, or judicial contingencies have brought them to treatment. But despite this problem, it is absolutely necessary to attempt to assess treatment motivation and to report results of that assessment in any study in which motivation for treatment could play a role in outcome.

Alcoholic analogues. Despite their omnipresence, alcoholics are not easy to locate for study. They are also not likely to be highly motivated to participate in psychological research (whose payoff to them may be unclear), are not always reliable in keeping appointments when they do agree to be subjects, and, when they are not drinking, they are apt to prefer working to participating in research. Because research designed to examine alcohol's effects on alcoholics can only include alcoholics in good physical and psychological health despite their chronic alcoholism, those who design such research find themselves with an even smaller pool of alcoholics ready, willing, and able to be research subjects.

For these reasons, researchers may choose to study *alcoholic analogue subjects*, who may be "problem drinkers" of one sort or another or, commonly, heavy-drinking college students. Though choice of such subjects is understandable, generalization from their behavior to that of alcoholics must be done with great care—if at all. For this reason, it is almost always preferable to study alcoholics than their analogues; it is practically impossible to control for all of the differences that separate alcoholics and nonalcoholics, some of which remain unknown. Among the most obvious of these differences are age, educational level, cognitive functioning, and rate of ethanol metabolism.

Above all, one must be chary about concluding that what is characteristic of the behavior of a group of problem or heavy drinkers is likely also to characterize the behavior of alcoholics—only more so! In all likelihood, such a conclusion is not justified.

The problem of treatment dropouts. Although the dropout problem for all kinds of psychological treatment is a serious one, it is especially so for alcoholics and drug addicts, both of whom are poorly motivated for treatment; variable in meeting vocational, familial,

and personal obligations; and, often, in poor control of their behavior. A recent study of more than 14,000 chronic alcoholics treated at 44 federally funded alcoholism treatment centers throughout the country (Armor, Polich, & Stambul, 1976) revealed that fewer than 15% of these clients continued in treatment as long as 3 consecutive months. Moreover, of the original sample of 14,000, 6-month follow-up data on only 2,371 clients were reported. Both figures suggest something of the scope of the attrition problem facing the addictions treatment outcome researcher.

Given, then, that substantial numbers of alcoholics and drug addicts drop from treatment in its midst and that as many more who complete treatment cannot be located for follow-up, how is one to compare two or more treatment methods on both the short and long term? To begin with, one must include in any statistical analysis of differences among treatment groups subjects who dropped from treatment; these subjects should be considered treatment failures regardless of the rationalizations some may have given for the decision to terminate. The unintentional deception that can result if this rule is not followed is illustrated by an article published a few years ago comparing groups of alcoholics receiving two "active" treatments, both involving the administration of electric shock, and two "inactive" placebo treatments. On comparing the four groups in terms of average length of abstinence immediately following treatment, the study's authors concluded that one of the active treatments was associated with significantly longer periods of abstinence than the other three treatments. Inspection of the data on which this conclusion was drawn, however, reveals that 13 active treatment subjects dropped from treatment in its midst, whereas only 1 placebo treatment subject did so; this fact was not taken into account in the significance testing of posttreatment abstinence rates, which only compared subjects who had completed treatment. Since many of the active treatment subjects dropped from treatment because they found electric shock aversive, to conclude from the abstinence rates of subjects who were motivated enough to endure shock and remain in treatment that the active treatment

was more effective than the placebo is deceptive, however unintentional.

Although most readers doubtless agree that patients who drop from treatment must be considered treatment failures for comparative purposes, it is more difficult to find agreement on how to handle treated subjects who cannot be located for follow-up. Is one to conclude that all subjects who cannot be found at a follow-up interval have returned to drinking or drug taking, have remained "dry" or "clean," or are using alcohol and drugs in about the same proportions as subjects who could be located? Though all three stances are defensible, the most conservative approach to this problem is to consider all patients unlocated at follow-up to be treatment failures (a position recommended by the American Medical Association, 1956; Pattison, Sobell, & Sobell, 1977; Sobell, 1978).

Before having to accept this admittedly unsatisfactory solution to the problem, though, one ought to take every step necessary to ensure that as many patients as possible are available for follow-up assessment. Ways to achieve this desirable goal are summarized later in this article in the section entitled *Follow-up*.

Who to study? It is inevitable that most of the subjects in alcoholism and drug treatment research will be male skid-row or "blue collar" alcoholics and ghetto-dwelling drug addicts. The reasons are that these individuals are often unemployed and, hence, available for intensive, long-term study; even if employed, they are more likely to be clients of publically funded clinics whose clientele is more available to researchers than are the patients of private psychologists and psychiatrists. Another is that this population of alcoholics and drug abusers is more likely than any other to reach the attention of the judicial system, and subsequently to be remanded to treatment by the courts; such court referrals constitute an important source of subjects for treatment evaluation studies. This is especially important, since it is clear that data on treatment outcome for court-referred drug addicts—whatever their socioeconomic status—cannot readily be generalized to drug abusers referred for different reasons. Unfortunately, few alcohol or drug

treatment reports include explicit descriptions of referral sources.

As a result of these and other similar factors, most of our data on drinking patterns, patterns of drug use, and response to treatment are from this group of subjects, even though it is not representative of the total universe of drug abusers and alcoholics. It has been estimated, for example, that fewer than 5% of all alcoholics are of the skid-row variety (Armor et al., 1976).

With these observations in mind, we offer two remedial suggestions: (a) Every effort should be made to study socially and economically advantaged alcoholics and drug abusers as well as more readily available groups. Sources of such persons include autonomous Alcoholics Anonymous groups; private clinicians who might agree to cooperate with researchers they know and trust; and private hospital administrators, whose interest in research collaboration might reflect their wish to gain professional credibility by associating with a university's research efforts. (b) If the usual groups of skid-row alcoholics and destitute heroin addicts are the only populations available for study, the researcher must make clear that generalizations from his/her data can only be to comparable groups of intellectually and vocationally limited individuals, that few alcoholics and drug-dependent individuals are as impoverished in so many ways as are these overstudied individuals.

Procedure: Comparative Treatment Studies

Group versus single-subject designs. The same design dilemma faces the alcoholism or drug treatment researcher as confronts any other clinical researcher who must choose between group and single-subject designs. Group designs permit more comfortable generalization of findings from one population to another, because they enable statistical testing of differences in the efficacy of one treatment procedure and another among substantial groups of individuals. At the same time, group designs sacrifice the fine-grained analysis of the temporal dynamics of behavior change provided by single-subject designs. As important, they do not permit the "return to

baseline" implicit in the single-subject ABA design that is necessary to establish that it was the treatment, rather than time, motivation, or expectancy, that brought about the observed changes in behavior.

Because so much of the research on alcoholism treatment by psychologists during the past 5 years has been behavioral, much of the literature reports single-subject designs. By contrast, the older literature reported results predominantly from group designs. It is possible, in fact, to retain the virtues of both designs by ensuring that group designs provide for thorough and reliable pretreatment and posttreatment assessment of behavior, carefully matched experimental and control treatment subjects, and suitably prolonged follow-ups.

Several recent studies comparing alcoholism treatment methods have achieved this desirable blending of the strengths of single-subject and group designs, among them comparisons of abstinence-oriented and controlled-drinking-oriented behavior modification programs (Sobell & Sobell, 1976), behavioral family counseling, electrical aversion, covert sensitization, and systematic desensitization (Hedberg & Campbell, 1974), and two broad-spectrum behavioral treatment packages (Vogler, Compton, & Weissbach, 1975). All three projects provided for comprehensive pretreatment and posttreatment assessment of drinking behavior and vocational, familial, and interpersonal effectiveness; follow-up periods extending to or beyond a year, accompanied by procedures to minimize subject attrition during the follow-up period; treatment groups matched for relevant demographic and treatment motivation variables; and careful attention to comparability of "active" and "placebo" treatments. Unfortunately, the blending of constructive design elements contained in these studies is not generally characteristic of the field.

Who are the therapists? It is important to ensure that the treatments contrasted in comparative treatment studies be provided by comparably trained, equally committed therapists. To compare treatment outcomes when one treatment is given by experienced therapists and the other by graduate students, or when one is administered by clinicians com-

mitted to the treatment they are providing while the other is offered by men and women unconvinced that what they are doing has value, represents poor research design. Yet many researchers have made precisely this design error when comparing one or another combination of innovative therapeutic approaches with what is euphemistically termed *standard hospital milieu therapy*. The latter, which may include alcohol or drug education, group therapy, occasional personal counseling, and the opportunity to participate in an Alcoholics Anonymous or Synanon group, is usually provided by undertrained, underpaid state hospital workers whose enthusiasm for their work, insight into its value, and level of clinical training are rarely equal to those administering the new treatment approach. When the new therapeutic package turns out to be more efficacious than the standard one in such comparative studies, one cannot be certain that it was actually more active or that it was provided by committed therapists whose enthusiasm for their work was infectious.

We recommend that no new therapeutic package be compared to "standard hospital treatment milieu," so often a euphemism for virtually no treatment at all. Instead, the separate components of novel treatment packages might more profitably be compared to each other, as well as to the package as a whole, in this way permitting assessment of each component's contribution to the overall package's effectiveness. For those researchers wishing to compare their efforts to some "standard" success rate for alcoholism treatment, two choices are among those possible: Armor et al.'s (1976) recent survey data, suggesting that 70% of the clients treated at typical alcoholism clinics across the country show short-term improvement in drinking rate, make for rigorous comparisons; Ditman's (1967) earlier conclusion that the success of Alcoholics Anonymous, often the alcoholic's initial treatment resource, is only between 30% and 35% makes for much more comfortable ones. Our own view of the matter is that abstinence beyond a year by 40% or more of patients treated by *any* technique surpasses current expectations.

Treatment variables. To justify meaning-

ful comparisons among different treatments, it is axiomatic (a) that all patients in all treatment groups must have received about the same number of hours of individual and group treatment and (b) that the intervals between treatment sessions must have been comparable. It is necessary to ensure comparability of treatments in this way because there is a considerable clinical treatment literature that attests to the therapeutic impact of the relationship between therapist and patient, an impact independent of the therapeutic methods that the therapist chooses to use (Smith & Glass, 1977).

In practice, this straightforward control procedure can present problems. Comparing an experimental treatment to "standard hospital milieu" treatment, for example, might prove impossible if this control is taken seriously; Most experimental treatment programs provide individual or group treatment—or both—administered by highly trained and experienced clinical researchers and their students, whereas standard treatment, customarily administered by hospital workers whose training and motivation may be inferior, is also likely to involve much less 1:1 contact and small group treatment. In similar fashion, comparison of methadone maintenance to psychotherapy is frequently confounded, since methadone programs usually involve the drug addict in less treatment time and less intimate therapist contact than do most psychotherapeutic treatments.

A related matter has to do with the scope of treatment issues addressed—the range of problem behaviors confronted. Consider how different the scope of treatment was for experimental and control subjects in a recently reported, widely cited behavioral treatment package for alcoholics:

Experimental Subjects: Procedures included subjects being videotaped while intoxicated under experimental conditions, providing subjects when sober with videotape self-confrontation of their own drunken behaviors, shaping of appropriate controlled drinking or nondrinking behaviors . . . the availability of alcoholic beverages throughout treatment, and behavior change training sessions. [The latter] is a summary phrase to describe sessions which concentrated upon determining setting events for each subject's drinking, training the subject to generate a series of possible alternative responses to those

situations, to evaluate each of the delineated alternatives for potential short- and long-term consequences, and then to exercise the response which could be expected to incur the fewest self-destructive long-term consequences. Behavior change training sessions consisted of discussion, role playing, assertiveness training, role reversal or other appropriate behavioral techniques.

Control Subjects: Control subjects received conventional treatment procedures which could include group therapy, chemotherapy, Alcoholics Anonymous, physiotherapy and other traditional services. (Sobell & Sobell, 1973, p. 601)

Although the range and diversity of potential treatments available to control subjects in this study could have been as great as those provided to experimental subjects, one is left with the distinct impression that the scope of treatment offered to experimental subjects—the specific problem areas that the treatments were designed to confront—was both better targeted and more comprehensive than that available to control subjects. In other words, *the treatment package offered to experimental subjects was not only different from but better than that provided control subjects.*

One resolves this common design problem by confronting the fundamental difficulty of premature comparison of the efficacy of comprehensive treatment packages, by resigning oneself to the necessity to compare the components of a treatment package separately before attempting to assess the overall efficacy of the package itself. It was this strategy that guided Wilson, Leaf, and Nathan's (1975) assessment of the efficacy of electrical aversion, a common element of broad-spectrum behavioral treatment for alcoholism. Their subjects received lengthy conditioning trials of electrical aversion, followed directly by ad libitum access to beverage alcohol. When subjects showed absolutely no evidence of conditioned aversion to ethanol, by drinking during the posttreatment period with the same enthusiasm for alcohol that they had shown pretreatment, it was concluded that electrical aversion, either by itself or within a broad-spectrum treatment package, did not have the therapeutic power many had presumed it to have.

Follow-up. Although it is obvious that the longer the follow-up interval posttreatment,

the more sure one can be of data on treatment efficacy, no one knows how *short* the follow-up period can be and still reflect ultimate treatment efficacy. Nonetheless, most alcohol and drug researchers question any follow-up interval that fails to extend to 1 year or more posttreatment. They believe that such an interval is inadequate to assess the long-term effects of treatment for alcoholism or drug dependence, given that many alcoholics and drug abusers spontaneously modify or cease drug or alcohol ingestion on their own for periods extending beyond a year. We believe that a 2-year follow-up of treatment for alcoholism or drug dependence is necessary to provide a suitably comprehensive view of the power of the treatment to effect lasting change.

A 2-year follow-up period, however, presents formidable subject attrition problems. Given the transient nature of the existence of many alcoholics and drug addicts, how does one keep contact over that time with men and women whose residences, jobs, and lives change so much and so often? Sobell (1978), a clinical researcher with great experience in maintaining contact with alcoholic clients over lengthy follow-up intervals, suggests the following set of coordinated steps to minimize attrition of subjects during a follow-up period: (a) Allow enough time and develop enough persistence to locate as many follow-up subjects as possible; do not settle for a majority of subjects or even for most of them. (b) Explain to subjects at the end of treatment why follow-up contacts are scheduled, when they can expect to be contacted for follow-up, the kinds of information to be requested, and how this information will be used. (c) Identify as many collateral sources of information about subjects as possible during treatment. (d) Maintain continuity of contact with patients during the follow-up interval by keeping in touch every few weeks, even if follow-up information is not required until 6-month or 1-year marks. (e) Be prepared to consult official records (e.g., jail, hospital, welfare, driver records, etc.) to locate lost subjects. Parenthetically, maintaining this kind of frequent contact for follow-up purposes also serves as an important source of low-cost "continuing care"

that may help maintain therapeutic gains first achieved during treatment. In this instance, then, good research design and good patient care go hand in hand.

A frequently ignored follow-up issue of relevance to both alcohol and drug treatment studies is that a treatment program may be highly effective in attaining desired goals while patients are actively involved in the program, only to appear to fail when patients return to nonsupportive or destructive environments. Unfortunately, a follow-up assessment 3 or 6 months posttreatment will not reveal this Treatment \times Environment interaction (Gotestam, Melin, & Öst, 1976). Under these circumstances, assessment of outcome immediately after treatment has ended and then again during a follow-up period much more clearly delineates dynamics of improvement and determinants of relapse.

Outcome measures. A variety of direct and self-report measures of drinking behavior have been developed. The Cahalan quantity-frequency index (Cahalan & Cisin, 1968), the Michigan Alcoholism Screening Test (MAST; see Selzer, Vinokur, & Wilson, 1977), and Marlatt's behaviorally oriented Drinking History questionnaire (Marlatt, 1975) are the most widely used self-report measures of drinking. Although use of such measures opens the investigator to criticism on grounds of the relative unreliability of self-report data, several studies have recently reported that alcoholics' and drug addicts' self-reports on drinking and drug ingestion may be far more accurate than previously believed (Cox & Longwell, 1974; Sobell, 1978; Homer & Ross, Note 1). Regardless of these data, however, we prefer direct measures of drinking behavior, including blood alcohol determinations taken at unannounced intervals (e.g., Miller, 1975), taste test or other drinking analogue methods (e.g., Marlatt, Demming, & Reid, 1973), or, simply, ad libitum drinking opportunities (Schaefer, Sobell, & Mills, 1971). The latter two methods, however, cannot be used to assess dry alcoholics, since they provide the opportunity for alcohol ingestion; this assessment problem is considered in greater detail by Nathan and Lansky (1978). Whatever outcome measures are ultimately selected for use, the point discussed earlier in regard to

the issues of reliability and validity is relevant here as well: These measures are relatively uninterpretable unless reliability and validity estimates for the population under study are reported.

There are other measures of treatment outcome that relate less directly to drinking or drug ingestion. One of the most thorough tests of these pretreatment and posttreatment measures was provided by Armor et al.'s (1976) recent national study of 44 alcoholism treatment centers scattered around the country. A complex of vocational, marital, and social indicators of relevance to alcoholism were tapped; direct reports from employers, clinicians, relatives, and others in a position to comment on job stability and marital adjustment were elicited. In some instances, these indices of behavior change showed more dramatic improvement following treatment than did direct measures of change in alcohol consumption.

In similar fashion, treatment goals for drug abusers extend far beyond mere reduction of the frequency of drug abuse; goals are often set to include improved employment status, widened spheres of non-drug-related social contacts, and improved physical health (Anderson & Nutter, 1975; McCabe, Kurland, & Sullivan, 1975). As a result, pretreatment and posttreatment measures must tap information that directly reflects the status of these socially desirous variables, frequently a most difficult task.

Whichever combination of direct and indirect indicators of change-in-life functioning is chosen, it is important that follow-up intervals be circumscribed enough to permit reliable recall of the data requested. To ask an alcoholic or drug addict to recollect quantity and frequency of alcohol or drug ingestion or quality of marital or vocational adjustment over a 6-month or 1-year period with any reliability is obviously impossible; to request such recall for a 2-week period is both more reasonable and, likely, will prove more reliable.

Procedure: Other Studies

Nature of the analogue in analogue studies. One of the most common thrusts of alcohol-

ism research that is not treatment oriented involves the use of alcoholic analogues. Such research might describe "typical" drinking patterns of chronic alcoholics, college students, or middle-class women. It might investigate the effects of alcohol on psychological, social, or cognitive functioning. Or the research could inquire into the impact of one or another environmental variables, designed to induce stress or anger, for example, on consequent drinking. All of this research could be undertaken analogically. Typical drinking in the real world can be inferred from patterns of drinking in the laboratory; under certain circumstances, the effects of large amounts of alcohol on cognitive functioning can be predicted from the effects of small doses; in some cases, the impact of stress on drinking can be studied by first creating artificial stress in the laboratory—an environmental condition analogous to real-life drinking stress—and then measuring consequent drinking behavior.

Reasons for undertaking analogue research instead of research in the real world are many. Alcoholics and drug addicts are hard to find, even harder to study. Giving alcohol in large doses to anyone, especially to an alcoholic, is difficult; giving hard drugs to anyone, especially to a drug addict, is virtually impossible. For these and other reasons, analogue research on the addictions stands between no research and the researcher. But there are important caveats to observe in undertaking analogue research in this field. They include, above all, assuring oneself—and one's professional audience—that the analogue one has chosen to use is not stretched so far as to bear only vague resemblance to the phenomenon in the real world. For instance, the laboratory drinking behavior of college sophomores cannot be considered representative of the drinking of adults in neighborhood taverns or at home. Similarly, the absence of an impact on intelligence test performance of moderate blood alcohol levels during a single test session has little relevance to possible cognitive deficits suffered by long-term heavy drinkers. Finally, stress induced in a laboratory might not be at all comparable to stress in the real world, especially when the latter

stress derives from *things that matter* and the former stress does not.

The obvious solution to these potential problems is to avoid analogue studies, when possible. But when it is not possible to do so, as is so often the case, what then? In that event, one must document, to the extent possible, the nature of the relationship between the analogue and the real world. The burden of proof of the relevance of an analogue to the natural environment is on the investigator, not his or her audience!

Experimenter bias. By now virtually every psychologist knows of the pitfalls of experimenter bias, known to many as the "Rosenthal effect" (Rosenthal, 1966). In essence, experimenter bias refers to the unintentional bias that experimenters bring to their interactions with experimental subjects that can, in some cases, affect data.

Although it is doubtful that experimenter bias plays a more serious role in research on alcoholism and drug dependence than it does elsewhere, it can—and does—play a role that must be anticipated. Examples include the following: (a) In studies of free ad libitum drinking, especially those taking place in controlled laboratory settings, it is entirely possible for staff unintentionally to bias subjects toward either more or less drinking. This possibility is so real that we actively seek to reduce interaction between drinking subjects and staff to an absolute minimum in our own laboratory drinking studies. (b) In studies in which the effects of stressors on drinking or of alcohol on response to stressors is the focus, the investigator must ensure that the effects of the stressor derive from its real impact, not from his/her unintentional conveyance of expectations about those effects. In such studies, postexperimental questionnaires must affirm that the subject did perceive the stress stimulus as a stressor. (c) In studies in which alcohol's effect on other behaviors is being examined (e.g., its impact on projective responses, interpersonal facility, or psychomotor behavior), it is just as important to ensure that hypothesized effects are not translated into observed effects, because the experimenters betray their expectations to drinking subjects. To this end, careful inquiry at the conclusion of the study as to

subjects' perception of its intent is frequently most enlightening.

The demography of alcoholism and drug dependence. As emphasized above, it is crucially important to control for variables other than variety of alcoholism or drug dependence in comparative treatment studies. Similar controls—or, at the least, awareness of the importance of such variables as age, sex, race, and socioeconomic status when experimental controls are impossible—are also necessary in studies exploring the impact of alcoholism on behavior. To fail to account for these variables is to run the risk of attributing to alcoholism or drug abuse responsibility for a particular behavior, a Rorschach percept, a Minnesota Multiphasic Personality Inventory (MMPI) or Wechsler Adult Intelligence Scale response pattern—or a treatment outcome—when, in fact, these behaviors may derive instead from the complex of ethnic, educational, or socioeconomic factors associated with alcoholism or drug dependence.

Results

On reporting results. It is tempting, when reporting the results of a study, to be optimistic about their significance, even a bit grandiose about their staying power. Human nature being what it is, it is hard to be overly critical of the natural human tendency to see in one's own efforts what one might not see in those of others.

On the other hand, although overestimation of the significance of a new nodule on the backside of a personality theory can be tolerated, misleading, immodest, or unrealistic reporting of the results of comparative treatment studies goes beyond bad form. When read by persons unequipped to separate an inflated claim from a barely significant probability value, such reporting could result in the misapplication of unproven methods.

The point we wish to make here is a simple one: It is incumbent on the serious researcher to report data parsimoniously, modestly, and completely, even when data in their entirety are more confusing and less unequivocally interpretable than data that have been selectively pruned. Although improper presentation of data is a snare for every re-

searcher, it is particularly so in fields such as alcoholism and drug dependence. In these fields, little is known; the stakes are high for persons who develop viable theories of etiology or useful therapeutic approaches; and rapid, independent confirmation or disconfirmation of new findings is difficult. As a consequence, a series of revolutionary findings have swept the field, including several genetic theories of etiology, a variety of new, "sure fire" diagnostic methods, novel behavioral treatment procedures that do not require abstinence, and innovative prevention programs guaranteed to reduce prevalence of these disorders. Unfortunately, like similar claims made of new discoveries about the schizophrenias in the late 1950s and early 1960s, the light of day—and independent replication—has either diminished or disproved most of these epochal findings.

Although Job was not necessarily speaking of psychological science when he concluded that there is nothing new under the sun, it might be wisest to heed his words until, or unless, independent confirmation supports your Nobel-prize-winning discovery, especially if you work in alcoholism or drug dependence!

Clinical versus statistical significance. It is as possible to overinterpret statistically significant as marginally or wholly insignificant differences among groups, because statistically significant differences may fail to achieve clinical significance. Although not conclusive, the following list includes three instances: (a) Psychological test patterns that differentiate groups at .05 or .01 levels rarely prove helpful in differentiating for diagnostic purposes. For example, alcoholics and drug abusers often differ from nonpsychiatric controls or unselected psychiatric patients by scoring higher on the Depression, Psychopathic Deviate, and Mania subscales of the MMPI; to draw similar diagnostic distinctions on the basis of symptoms of depression, mania, and psychopathic behavior alone, however, is rarely sufficient. (b) Statistically significant differences in the efficacy of one treatment approach over another, no matter what the level of difference in efficacy or how it was judged, are inadequate bases for selection of treatment unless or until cross-

validation of the promising approach, with different therapists and different patient groups and in different settings, confirms the general utility of the technique. Electrical aversion, a promising behavioral technique that made excellent theoretical sense and showed exciting promise when first applied, has since proven itself to be of little value as a therapeutic technique on extensive cross-validation. Methadone maintenance may be in the midst of suffering the same ignominious fate. (c) Studies demonstrating the significant impact of a specific etiologic factor on a specific disorder do not, perforce, prove that every patient possessed of that factor will develop the resultant disorder or that every patient carrying that diagnostic label can point to that etiologic factor. In the case of alcoholism, for example, recent research by Goodwin and Guze (1974) strongly suggests the role of genetic factors in the etiology of alcoholism. Significantly more Danish children of alcoholic parents given up for adoption developed alcoholism than did children of nonalcoholic parents. But despite this significant difference in outcome, the contribution of the genetic factor was only partial: Some children of nonalcoholic natural parents became alcoholics as adults; most children of alcoholic parents successfully avoided alcoholism.

Do statistically significant differences among groups ever have significance clinically? In our experience, such differences have clinical significance only when all or most of one group shows one pattern and few or none of another does so; in such a rare event, however, it is doubtful that one would feel the need to point to statistical confirmation for such an obvious relationship. This issue, of course, is one of the touchstones of the applied behavior analysts, most of whom have chosen to dispense with statistics in favor of research designs permitting identification of the "active ingredients" of behavior change regimens capable of modifying a given target behavior every time it (or they) is applied.

Discussion

Issues of generalization. Throughout this article, we have urged the reader to adopt a

conservative, essentially modest, approach to his/her data and to claims or conclusions deriving therefrom. For the same reasons, we wish to suggest a spirit of modesty in the Discussion section of a research paper. Two essential features of this attitude are worth emphasizing: (a) Discussion of results might well begin with a section that details limits on generalization from the data reported. If only males over the age of 40 were studied and prior data suggest that the problem under investigation is not limited to that group, it is well to point out that conclusions from the research may refer only to older males, perhaps even older males from the geographic or sociocultural group studied (if those variables might also affect generalizability). (b) Even in the absence of specific methodological constraints on generalizability, it is wisest and most sound to limit the extent to which one lays claim for the widespread or universal relevance of one's findings. A host of variables specific to one's subject sample, procedure, or data analysis, unknown or undetected during the research, could later come back to haunt one. The classic example of such an embarrassment, of course, is the unfortunate team of biochemists who reported discovery of a "schizophrenic" blood portion, only to have to report some years later that their sample of schizophrenics had consumed so much coffee that the coffee's metabolic residuals had stamped their subjects' plasma as abnormal!

Bias in discussion. Beyond overblown claims of the merits of a new therapeutic approach or unwarranted generalizations beyond sample populations, the most common problem arising from discussion of alcoholism and drug dependence data comes when the author does not discuss data in terms of prior research on both sides of his/her position.

Although this approach to science sounds unthinkable, it is surprisingly easy to adopt a position, accept it fully, then view as well done and careful only work that supports that position. To this end, one of the most cherished, widely held views by alcoholism workers has long been that the only treatment goal for alcoholics can be abstinence. This position has continued to keep its supporters, of whom there are many, from more recent

data suggesting that conventional, abstinence-oriented treatment for alcoholism is relatively ineffective (Pattison et al., 1977) and that some alcoholics do return to a controlled pattern of drinking either after treatment or in its absence (Pomerleau, Pertschuk, Adkins, & Brady, in press; Sobell & Sobell, 1976). Nonetheless, one reads startlingly ad hominem criticisms of researchers who have acknowledged the possibility that the new data on controlled drinking might justify a change in thinking. A similar lack of objectivity characterizes those who hold to the belief that alcoholism is a medical disease, wholly or largely, despite evidence to the effect that social-learning mechanisms, sociocultural influences, and psychological phenomena also play important etiologic roles in the disorder.

Methodological Issues in Research with Correctional Populations

N. Dickon Reppucci and W. Glenn Clingempeel
University of Virginia

Methodological issues confronting psychologists who conduct research with correctional populations are examined. The article is divided into five major sections: (a) the intrusion of values; (b) problems with trait-derived methodologies in correctional population research, including inadequate construct validity, ignoring environmental influences and ignoring subjects; (c) naturalness and the problem of external validity; (d) recidivism; and (e) ethics. General recommendations are offered at the conclusion of each section.

The purpose of the present article is to discuss "methodological issues" confronting psychologists who conduct research with correctional populations. In the selection of issues for discussion—a necessarily value-laden process—we have chosen to focus on problems emanating from ignoring external validity considerations (e.g., In what ways can the findings be generalized?) and from the potentially constrictive impact of prevailing values and conceptual weltanschauung on research designs. The reader should not interpret this focus as indicating that internal validity (e.g., Did the experimental condition make a difference?) and/or data analysis issues (e.g., the use of univariate analyses when multivariate analyses are appropriate) are either unimportant or uncommon in correctional research. Such an interpretation would be erroneous. Rather, the decision to focus on the former issues, although not entirely excluding the latter, is based on the assumption that these latter problems are generally given center stage in methodological critiques of psychological research and that another similar critique would be less informative than the current attempt. The accuracy of this judgment is left to the reader.

In attempting to delimit this critique, sev-

eral constraints and qualifications should be underscored:

1. The problems discussed are not necessarily unique to research with correctional populations. Many, if not all, issues could just as easily be raised with regard to other involuntarily incarcerated populations, for example, mental patients. Indeed, some of the issues are salient for much of psychological research, in general, and for personality research with "clinical" populations, in particular.

2. Since there are recent excellent reviews of methodological problems of behavior modification and delinquency studies (e.g., Davidson & Seidman, 1974; Emery & Marholin, 1977) and of large-scale program evaluation research in correctional settings (e.g., Adams, 1974; Glaser, 1974; Sarri & Selo, 1974), these areas are not considered.

3. Only research actually conducted with subjects residing in correctional settings was examined. This constraint allowed exclusion of those studies focusing on experimental interventions with offenders subsequent to their release from a correctional facility.

4. The data for deriving and elucidating the issues discussed in this article are in no way all inclusive, being largely based on only two sources: (a) a scrutiny of unpublished articles reviewed by the first author over the past 5 years in his role as a consulting editor for the *Journal of Consulting and Clinical Psychology (JCCP)* and (b) an intensive

examination of all relevant studies published in *JCCP* and the *Journal of Abnormal Psychology* (*JAP*) during the last 10½ years (January 1967–August, 1977) (see Table 1).¹

5. Attention is focused on what we call the *personality discrimination* research paradigm, since, as is clear from Table 1, over 60% of the published studies examined were subsumed under this category. (The majority of unpublished studies submitted to *JCCP* also fell in this category.) In brief, this paradigm uses population subtypes (e.g., delinquents and nondelinquents, recidivists and nonrecidivists) as the independent measures and attempts to determine from an array of dependent measures (e.g., measures of impulsivity, delay of gratification, sensation

seeking, time perspective) those that discriminate between the groups.

This article is divided into five major sections. The first section examines the intrusion of certain value assumptions on the research enterprise and the methodological stagnation that we believe has resulted from these intrusions. The second section confronts three shortcomings fostered by trait-derived methodologies, including the problem of inadequate

¹ These two journals were selected for intensive examination because they are the two APA-sponsored journals most likely to publish research articles containing correctional populations and therefore of most potential interest to readers of this journal.

construct validity, the problem of ignoring environmental influences, and the problem of ignoring subjects. The third section focuses on external validity problems stemming from the failure to incorporate naturalistic dimensions in research designs. The fourth section outlines some of the difficulties with the much used recidivism measure. The final section provides a few comments on the ethics of research with correctional populations. Each section is concluded with one or more recommendations.

The Intrusion of Values

To suggest that values pervade every stage of the research enterprise from choice of problem and selection of research design to analysis and interpretation of data is only to repeat what numerous others have said before (e.g., Allport, 1940, 1943; Hudson, 1972; Sarason, 1975). Yet the failure to confront the potential impact of implicit value assumptions on the research process is a ubiquitous shortcoming endemic to much of social science research (Caplan & Nelson, 1973). In this section, attention is focused on a few specific conceptual-methodological constrictions engendered by values pervading research with correctional populations.

From the review of studies with correctional subjects (see Table 1), two major value premises emerged—(a) the assumption of offender deficit and (b) the assumption of discriminating traits. Although not exhaustive of value influences, these two assumptions permeated almost all of the research that was examined.

The assumption of offender deficit is based on the belief that something must be psychologically wrong with any person who has committed a crime (Brodsky, 1973). This assumption appears to have contributed to much research whose goal is the search for psychological or personality disorder in prisoners. As a result there is an overemphasis on disorder, psychopathology, and other negative characteristics. Unfortunately, this emphasis characterizes much behavioral science research with minority and/or "clinical" groups (Caplan & Nelson, 1973; Jourard, 1968; West & Gunn, Note 1). Recently, Caplan and Nelson

(1973) demonstrated this preoccupation in psychological research with black Americans. They examined all studies of black Americans appearing in the first 6 months of the 1970 *Psychological Abstracts*. In 82% of the studies that they classified, the nature of the research suggested personal deficits as the cause of difficulties for black Americans. They concluded that

the picture that emerges is one of psychologists investing disproportionate amounts of time, funds, and energy in studies that lend themselves, directly or by implication, to interpreting the difficulties of black Americans in terms of personal shortcomings. (Caplan & Nelson, 1973, p. 204)

The major point to be drawn from their analysis is the analogous one that the offender deficit assumption constricts the research questions asked and the methods used. Two major omissions, for example, of much of the psychological research on criminal behavior are (a) focusing on prisoner strengths, for example, studies of helping behavior or other positive characteristics, and (b) ignoring the potential impact of situational and environmental factors in precipitating the criminal act. These omissions are viewed as a by-product of the attribution of personal deficits. If the causes of delinquency are defined in negatively valenced, person-centered terms (e.g., impulsivity, inability to delay gratification), then the inclusion of positively valenced terms and situational or environmental factors in the research design is neglected.

The second pervading value premise, derived from nomothetic personality theory, is the assumption of discriminating traits. This assumption suggests that a set of trait dimensions is applicable to all persons and that individual differences are to be identified with different locations on these dimensions. Moreover, on specific traits (e.g., impulsivity, aggressiveness), correctional subjects are presumed to be distant enough on the same trait continuum to enable discrimination from non-correctional subjects. A corollary assumption is that these discriminating characteristics are relatively enduring and cross-situationally consistent. It is implied that the rank order of individuals on any trait should remain the same in all situations. This assumption has given rise to methods (as in the personality

discrimination model) that ignore person-situation interactions and the advantages of idiographic strategies for personality assessment and prediction. Elaboration of these omissions is discussed elsewhere in this article (see *The Problems of Ignoring Environments and Ignoring Subjects*). At this point, it is necessary only to emphasize that in our opinion, conceptions of the personality of criminal offenders as internal behavior dispositions have resulted in a constriction of methods, a correspondingly reduced predictive utility, and incomplete conceptions of criminal behavior.

Recommendation

Investigators should recognize that the value assumptions of offender deficit and discriminating traits underlie much of the psychological research with correctional populations. Future research should focus on strengths as well as weaknesses and the development of experimental designs that do not neglect environmental influences and person-situation interactions.

Problems with Trait-Derived Methodologies in Correctional Population Research

Recently, Endler and Magnusson (1976) have argued convincingly that personality theory differences are inextricably linked to differences in research strategies and measurement models. For example, research stemming from trait model assumptions includes methods (e.g., questionnaires, ratings, tests) that are often different from those methods stemming from operant-type situationism assumptions (e.g., behavioral response rates and behavioral checklists for functional analysis of individual behavior). This linkage of personality theory and methodology is crucial to our analysis.

As pointed out in the previous section, trait assumptions and concomitant methodologies have occupied a prominent role in personality research with correctional populations. The frequency of use of the personality discrimination model—with its potentially discriminating measures of traits obtained in similar situations through similar response

modes—is a testimony to the currently functional status of this preoccupation. Despite its popularity in correctional research, the assumptions of the trait model have been frequently assailed. For example, an abundance of empirical evidence tending to refute the cross-situational consistency assumption has emerged from three sources (Endler & Magnusson, 1976)—(a) research (partitioning the variance into person, situation, and person-situation interaction components) that demonstrates that person-situation interactions account for more of the behavioral variance than persons alone and situations alone (Bowers, 1973; Endler & Hunt, 1966; Endler & Magnusson, 1976; Mariotti & Paul, 1975; Moos, 1968, 1969; Rausch, Farbman, & Llewellyn, 1960); (b) correlational research strategies in which correlations of same traits in different situations are found to be moderately low (Hartshorne & May, 1928; Magnusson, Heffler, & Nyman, 1968; Rushton, 1976); and (c) studies (simultaneously including personality and situational variables as independent measures in the design) that reveal interaction effects rather than main effects as the true state of affairs (Baron, Cowan, Ganz, & McDonald, 1974; Cronbach & Snow, 1975). From a review of these and other relevant studies, various investigators have concluded that there is a paucity of empirical support for the assumption of cross-situational consistencies of behavior (Argyle & Little, 1972; Endler, 1973, 1975a, 1975b; Endler & Magnusson, 1976; Mischel, 1973, 1977). With the acceptance of this conclusion, the task in this section is to focus specifically on the limitations of trait-derived methodologies as they have been used in personality research with correctional populations. Three of these problems, construct validity, ignoring environments, and ignoring subjects, are examined in the following discussion.

The Problem of Construct Validity

One salient problem that emerges from the trait-derived personality discrimination studies is the lack of attention given to construct validity issues (Cronbach & Meehl, 1955). Messick (1975) defined construct validity as

the process of marshaling evidence in the form of theoretically relevant empirical relations to support the inference that an observed response consistency has a particular meaning" (p. 955). Campbell (1960) outlined two requirements of construct validity, which he labeled *trait* and *nomological* validity. Trait validity refers to the requirement that the domain of observables that purportedly measure a particular construct must demonstrate internal consistency when put to the empirical test. This means that measures of the same construct must correlate highly with one another in individual difference studies and/or be similarly affected by experimental treatments. Nomological validity refers to the requirement that the measures of one construct behave in accordance with the network of relations to other constructs as derived from a formal theoretical system.

The trait validity requirement suggests that two or more measures of a personality dimension (e.g., impulsivity) should be substantially interrelated. For example, if institutionalized delinquents were to exhibit more impulsivity than nondelinquents on the Barratt Impulsivity Scale (Barratt, 1959), then evidence for construct validity would be obtained if this greater impulsivity also manifested itself on a second measure (e.g., the Hirschfield Impulsivity Scale; Hirschfield, 1965). In addition, both measures of impulsivity should behave similarly with regard to discriminating a delinquent from a nondelinquent sample. Construct validity could be questioned if the delinquent sample scored significantly different from the nondelinquent sample on the Barratt Impulsivity Scale but no differences or the reverse finding emerged on the Hirschfield Scale.

Although it is important that measures of the same construct exhibit a convergence and behave similarly, Campbell and Fiske (1959), in a classic, albeit often ignored, article, maintained that construct validation requires evidence of discriminant as well as convergent validity. Evidence for discriminant validity is revealed when measures of one construct are shown to have weak interrelations with measures of distinctly different constructs. Adopting the discriminant validity requirement, evidence for construct validity would

be weakened if personality measures of one dimension (e.g., impulsivity) correlated too highly with personality measures of another (e.g., nurturance). In the articles examined, the concept of discriminant validity was never mentioned. Clearly, a problem with the research that seeks to determine the extent to which correctional subjects differ from non-correctional subjects on some construct dimension is the failure to use multiple measures of both the focal construct and different constructs. As such, there tends to be little evidence for either convergent or discriminant validity in most studies of correctional populations.

A second construct validity problem of the personality discrimination studies hinges on the failure to take into account that each measure of a construct represents a trait *and* a method unit. The fact that two measures of impulsivity are interrelated may reflect only that they were measured by the same method (e.g., self-report) and not that they "tap" the same construct. Moreover, the reliance on such methods as self-report questionnaires and rating scales in the personality discrimination studies suggests the possibility that the observed consistencies may be more in response to method constraints than true differences on the construct. It is possible, for example, that an "oppositional" or "deviation" response set in which correctional populations choose responses that they believe differ from expectations could account for consistent performances on self-report questionnaires. Campbell and Fiske (1959) proposed the multitrait-multimethod matrix as a solution to both the convergent-discriminant validity problem and the problem of method-trait confounds. In this triangulation method, two or more traits are correlated with two or more methods. This procedure would suggest, for example, that the two traits, impulsivity and hostility, be measured by at least two methods (e.g., self-report and behavioral observations). Evidence for convergent validity would be obtained if the correlation of the same trait (e.g., impulsivity) by different methods (e.g., self-report and behavioral observation) was high. Evidence for discriminant validity would be obtained if (a) the same trait/different method (e.g., impulsivity

by self-report with impulsivity by behavioral observations) correlations were higher than different trait/different method (e.g., impulsivity by self-report with nurturance by behavioral observations) correlations, and, most importantly, (b) the same trait/different method correlations should also be higher than different trait/same method (e.g., impulsivity by self-report with nurturance by self-report) correlations. In effect, evidence for construct validity is obtained when measures with only trait variance in common exhibit higher correlations with each other than measures with common method variance and measures with neither trait nor method variance in common.

In summary, multitrait-multimethod techniques have seldom been used in research with correctional populations. As a result the construct validity of those measures in current use for discriminating correctional from noncorrectional populations remains uncertain at best. Although recognizing that evidence for construct validity is obtained when measures of a particular construct consistently discriminate between population groups presumed different on that construct, we contend that certain facets of the construct validation process have been paid relatively little attention. It is perhaps worth noting that in one study (Saunders, Reppucci, & Sarata, 1973) that attempted to marshal evidence for the construct validation of impulsivity as a trait characterizing delinquents, the investigators concluded that there was no evidence for the hypothesis that delinquent behavior is related to impulsivity or that existing measures of impulsivity tap the same dimension. Although the process of construct validation is a time-consuming venture, requiring multiple studies and the gradual weaving of a net of circumstantial evidence around a construct, its importance should not be underestimated. Personality labels that are supposedly descriptive of inherent traits of correctional populations often contribute to decisions regarding incarceration and to the development of intervention programs.

Recommendation

Increased attention in personality research with correctional populations should be given

to the construct validation process. As a minimum requirement, research designs should include multiple measures of each attribute or construct under investigation with those measures reflecting at least two different methods. Correlations among measures should be obtained.

The Problem of Ignoring Environments

The main criticism of the trait model has been its empirical neglect of situational factors as they affect an individuals' behavior (Endler & Magnusson, 1976). Consistent with this contention, the frequent use of trait-derived methodologies in correctional population research has resulted in the ignoring of possible interactive influences of environmental and situational factors in research designs. Significant predictive and generalizability limitations have been the consequence. This "problem of ignoring environments" has manifested itself in at least three forms in the personality discrimination studies and one form in the adjustment prediction studies.

First, with an assumption of cross-situational consistency ostensibly prevailing, personality discrimination studies have monitored a narrow universe of response modes in a narrow universe of situations. In a typical study, for example, subjects consisting of either matched groups of correctional population subtypes (e.g., neurotic and psychopathic delinquents) or a correctional group and a noninstitutional nonoffender control (e.g., high school students) are administered individually or in small groups an array of self-report questionnaires. Any differences that emerge between the groups are viewed as relatively stable and situation-free personality characteristics. The possible differential influences of situational factors are not considered. This holding of situations constant within and between studies has sustained a bias toward proving the trait notion (therefore increasing the likelihood of positive results).

Although incarcerated delinquents may, in fact, prefer immediate over delayed gratification more so than nonincarcerated nondelinquents as assessed by responses to hypotheti-

cal questions, the relative position of these groups on the delay of gratification continuum may shift as situational factors change (e.g., as the delinquents are released). In fact, Mischel (1973) has pointed out that to predict a subject's delay of gratification behavior, one may need to know such moderator variables as how old he/she is, the experimenter's sex, the particular objects for which the subject is waiting, and the consequences of not waiting. Given the possible influences of similar situational variables and their potential interaction with personality variables, the predictive utility or generalizability of good discriminators may be significantly impaired.² What is neglected in trait-derived methodologies is the attempt to answer the question, How are persons who end up in prisons different from each other and from noncorrectional populations with regard to specific personality characteristics as measured across specific situations? Clearly, then, to determine Personality \times Situation interactions, there is a need to incorporate both situational and personality variables as independent measures in research designs.

A second form of ignoring environments centers on the inadequate description of the experimental situation itself. The typical personality discrimination study cursorily mentions that an experimenter (whose characteristics are not described) administered a series of questionnaires (or tasks) in one or more settings (which are also usually not described) to two or more groups of subjects. Both internal and external validity problems may result. The internal validity problem is that the microsetting of the experiment, including the personal characteristics of the experimenter, may interact differently with the groups and significantly influence any observed group differences. The external validity problem is that inadequate descriptions render generalizability across experimenters, situations, and tasks a most hazardous business.

One area of inadequate description focuses on the experimenter. Although various experimenter characteristics have been shown to have demonstrable effects on the behavior of subjects in experimental situations (e.g., Barber & Silver, 1968; Rosenthal, 1963, 1968), McGuigan's (1963) characterization of the

experimenter as "the neglected stimulus object" certainly holds for the studies reviewed for this article. The fact that such basic experimenter characteristics as sex, age, and attractiveness may differentially affect the performance of incarcerated versus nonincarcerated males and/or females is simply not taken into account. In only 1 of the 28 published personality discrimination studies was there any description of the experimenter. This prevailed despite the fact that in 19 of these studies, subjects were evaluated individually—a situation that permits potentially greater experimenter impact. Moreover, although 18 of these studies had multiple authors, which presumably means a high likelihood of multiple experimenters (McGuigan, 1963), no studies attempted to investigate experimenter characteristics as an independent variable. This state of affairs seems increasingly dubious in view of a recent wave of investigations demonstrating that different experimenters obtain significantly different results with different subjects (Rumenik, Capasso, & Hendrick, 1977; Silverman, 1974; Silverman, Shulman, & Wiesenthal, 1972).

Neglecting the effect of experimenter characteristics engenders an internal validity problem; namely, the same or different experimenters may affect the performance of subjects in different groups in different ways. Stewart and Resnick's (1970) verbal conditioning study illustrates how this difficulty might manifest itself. These authors compared 33 incarcerated delinquent males with a control group of 33 boys from a nearby high school on a task measuring conditionability of aggressive and dependency verbs. All subjects were tested individually by an experimenter (or experimenters) who was (were) not described. In accordance with predictions, the delinquent group rejected the dependency verbs more so than did the nondelinquent group. The authors concluded that delin-

² A particular measure may reveal a highly significant difference between groups (and thus be a good discriminator) and yet be a poor predictor. Therefore, the discrimination-to-prediction leap should only occur after empirical investigations have confirmed the predictive utility of good discriminators.

quents found it more difficult to express dependency behavior than nondelinquents. Although not necessarily an unreasonable conclusion given a recognition of generalizability limitations, it is nonetheless quite possible that undescribed experimenter(s) characteristics were a (or the) major contribution to performance differences between the two groups. For example, depending on the experimenter's age, sex, and perceived status, he or she may have engendered less (or more) cooperation from the incarcerated delinquent group than from the high school group. Thus, differences between the groups may have resulted from the type of experimenter(s) used rather than because of personality differences between the boys. The point is that we do not know, because no information regarding the effect of experimenter characteristics was provided.

Experimenter neglect also constitutes an external validity, generalizability of findings, problem. Levine (1974) captured the crux of this concern:

The generalization possible from any experiment is limited to the set of conditions that includes a definition of that universe of experimenters and their behavior, of which the experimenters used in the experiment are a sample taken according to a well-defined principle of sampling. (p. 663)

Beyond the ignoring of possible experimenter effects, there tends to be both inadequate observation and description of the microculture of the experimental situation. The physical characteristics of the testing situation, including the behaviors of experimenter and subject that are seemingly peripheral to the study, and the nature of the rapport-establishing process, may singly or in combination exert subtle influences. Yet, in only a few of the studies examined were these dimensions adequately described. While recognizing that factors of this nature have allegedly been held constant and thus may not have significantly affected the results of the published personality discrimination studies, we also recognize that negative results and inconsistencies have a habit of not getting published. Moreover, the possible influences of higher order interactions become more important as one ventures beyond same situation/same response mode investigations to

develop studies that compare different subject types across different situations and that use more naturalistic, nonreactive measures. While realizing the impossibility of incorporating a multitude of potential moderator variables into any single experimental design, we suggest that a more ethological perspective—with a concomitant sharpening of observational and descriptive skills—may be useful in the understanding of inconsistencies and the possible influences of higher order interaction effects.

The primary concern is that researchers avoid misinterpreting Morgan's canon. As Cronbach (1975) stated:

From Occam to Lloyd Morgan, the canon has referred to parsimony in theorizing, not in observing. The theorist performs a dramatists' function; if a plot with a few characters will tell the story, it is more satisfying than one with a crowded stage. But the observer should be a journalist, not a dramatist. To suppress a variation that might not recur is bad observing. (p. 124)

The ignoring of the impact of correctional institutions on the behavior of offenders signifies a third form of environmental neglect. This neglect spawns two kinds of problems for personality research with correctional populations. The first problem centers on the failure in studies which search for discriminating personality characteristics of criminal offenders to extricate the effects of institutionalization from the effects attributable to offender characteristics. The subset of personality discrimination studies that compares institutional and noninstitutional populations illustrates this problem. In only 1 (Landau, 1976) of the 10 published studies was there any attempt to control for the impact of institutionalization (independent of subject characteristics) on performance of the dependent measures.

Thus, differences that have emerged between correctional and noncorrectional populations may be more a function of the impact of institutionalization than of differences between the groups on particular personality characteristics. Certainly commentaries on the possible profound effects of institutional environments on behavior (e.g., Goffman, 1961; Zimbardo, 1973) alert us to this likelihood. Landau (1976), in a study of time ori-

entation, recently attempted to remedy this problem. He included subject groups of institutionalized delinquents, noninstitutionalized delinquents (delinquents on probation), institutionalized nondelinquents (soldiers), and noninstitutionalized nondelinquents (students in a vocational training school). He also controlled for length of institutionalization for the incarcerated delinquents and the soldiers. The results provided strong evidence for the independent effect of institutionalization on various aspects of past, present, and future time perspective. Although (as might be expected) the army proved to be a milder form of institutionalization than prison, the effect of institutionalization was nevertheless substantial. Landau (1976) concluded that

this study provides additional evidence of the strong and measurable effect of institutionalization on various aspects of time orientation. This should be considered as a significant example of the possible effect that salient situational factors may have on characteristics and behaviors that are too frequently considered as stable and situation-free personality traits. (p. 757)

The second problem associated with the ignoring of institutionalization effects is the problem of inducing comparability of research findings conducted in different correctional institutions. The problem is accentuated by empirical evidence suggesting that correctional institutions differ on a number of dimensions (e.g., the treatment-security continuum) and that these differences are reflected in their effects on inmates (Moos, 1975; Street, Vinter, & Perrow, 1966). For example, Street et al.'s (1966) comparative evaluation of six correctional institutions revealed that institutional differences in treatment goals and philosophies were significantly related to inmate attitudes toward the total program, staff, other inmates, and themselves. Institutions with different orientations (e.g., control and obedience, reeducation and development, or treatment) clearly had different effects on their inmates. Moreover, although some of the variance could be accounted for by characteristics of the inmate populations, the independent effects of the organizations and their different orientations were pronounced. Additional evidence of correctional institution diversity comes from Moos's

(1975) cluster analytic derivation of six distinct institution types vis-à-vis the Correctional Institutions Environmental Scale (CIES). The major point is that regardless of whether the CIES, structural-organizational assessments, and/or alternative institutional description methods are used, institutional description strategies of some form are required if researchers earnestly seek comparability of research findings obtained in different correctional institutions.

Furthermore, it should be emphasized that correctional institutions are not homogeneous settings but contain a diversity of subsettings or situations, some of which are common across institutions, whereas others may be unique to a specific institution. Therefore, future researchers should elucidate and dimensionalize the crucial situations within and between correctional institutions. With regard to methods, Magnusson and Ekehammar's (1975) suggestion that we study *situation perception* (the meaning that an individual assigns to a situation), *situation reaction* (based on individual's responses to situations), and the relationship between these dimensions seems particularly worthy of adherence. The Person \times Situation interaction studies could then take the form of more naturalistic studies of person subtypes across actual situations within the institution. An important caveat is in order. The study of Person \times Situation interactions within correctional institutions will not likely give us much information about Person \times Situation interactions outside of the institutional setting. Obviously, relative to the extrainstitutional environment, in prisons the number of available situations as well as the freedom to choose among and capacity to change such situations is markedly delimited. Thus, there should be no expectation that research with incarcerated offenders will shed much light on the question of which specific Person \times Situation interactions outside the prison will be likely to result in the commission of which specific law-violative behaviors.

The major form of ignoring the environment in the adjustment prediction studies³

³ Adjustment prediction studies contain an array of personality, demographic, and institutional per-

has been the lack of attention paid to characteristics of the postinstitutional environment to which the correctional subject returns. Typically, the array of predictors of recidivism and postinstitutional adjustment have consisted of demographic, personality, and institutional adjustment measures. The availability of formal support systems (e.g., jobs, recreational facilities, financial resources, educational opportunities) and informal social networks (e.g., family, extended kin, friends), both of which may have a significant impact on the process of postinstitutional adjustment (see, e.g., McArthur, 1974), are seldom included in the prediction equation. Recently, Mischel (1977) has argued in a corresponding situation with mental patients that "accurate predictions of posthospital adjustment require knowledge of the environment in which the ex-patient will be living . . . rather than any measured person variables or in-hospital behavior" (p. 251).

Perhaps the best example of the inability of the typical psychological and demographic data to predict the future behavior of prisoners and others is found in the studies of the prediction of violent behavior (Megargee, 1970; Monahan, 1976; Wenk, Robison, & Smith, 1972). Not only has univariate analysis proved woefully inadequate, but there is also evidence to suggest that combining a multitude of person-centered predictors using sophisticated multivariate analyses is insufficient (Monahan, 1976). Most studies indicate a false positive prediction rate of over 80%, and the most accurate prediction of true positives (46%) still mispredicted 54% of the subjects (Monahan, 1976). In addition, Heller and Monahan (1977) pointed out that "the studies that report the highest percentage of true positives are generally those with the weakest methodologies" (p. 137). With the prediction difficulties encumbering person-centered approaches to violence prediction, recommendations have surfaced that ecological evaluations (e.g., predicting which situa-

tions will elicit violent behavior) replace the more common individual-oriented strategies.

Recommendations

1. Psychologists should adopt a cautious approach to inferring behavioral consistency based on responses to a specific task under a specific set of experimental conditions. Adequate descriptions of the experimental situation should be provided. When possible, multiple situations should be incorporated into the research design as independent variables. Data analysis should account for Person \times Situation interactions.

2. Adequate descriptions of the experimenter(s) should be provided. When possible, multiple experimenters should be incorporated into the research design as independent variables.

3. The factor of institutionalization should be controlled for in the experimental design. In addition, institutional description strategies (e.g., structural-organizational assessments) should be used to facilitate comparisons of correctional institutions and their differential effects. Future research should begin to dimensionalize the important situational variables within and between correctional institutions and to incorporate these variables in Person \times Situation studies. Finally, psychologists should proceed with extreme caution, if at all, in drawing conclusions about extrainstitutional Person \times Situation interactions from interaction studies conducted within the correctional environment.

4. Ecological evaluations that incorporate measures of the postinstitutional environment of prisoners, such as existing support systems and social networks, should become a standard part of adjustment prediction studies.

The Problem of Ignoring Subjects

A third pervasive problem of trait-derived methodologies is the problem of ignoring subjects. Partially as a result of the preoccupation with the nomothetic assumption that a set of trait dimensions is universally applicable and that all individuals can be identified with different locations of these dimensions, the correctional subject (as most others) has

formance variables in an attempt to determine the best predictors (through multiple regression analysis) of such criterion variables as postrelease adjustment and recidivism rates.

been neglected as an expert on his/her own behavior.

In not one of the studies listed in Table 1 were the subjects asked about their perceptions of, attitudes toward, or behavior in the research in which they were participants. Yet, subjects, in most cases are not passive recipients, even if cooperative; rather, they will develop hypotheses about the nature and purposes of the investigation. These hypotheses may be interpreted as demand characteristics that influence the subject's behavior and responses.

One potentially problematic demand characteristic is the general attitude of the correctional subject toward research and the concomitant motivation for participation. In comparison with free-world citizens, the attitudes of prisoners toward participation in research has been overwhelmingly positive (Wilson & Donnerstein, 1976). Correctional subjects may believe that participation in research is an indication of "good behavior" and therefore linked to getting out. Another possibility is that prisoners are motivated to participate in research by their boredom and the generally negative aspects of prison living (Brodsky, Note 2).

A second potential demand characteristic problem has been referred to as multiple treatment inference (Campbell & Stanley, 1963). The essence of this difficulty is that the effect of prior treatments and research participation is not erasable. This refers to multiple treatments in the same experiment as well as to research experience in other experiments. Brody (Note 3) provided an example of this problem. In an attempt to manipulate the choice of a delayed and immediate reward for an institutionalized delinquent and a noninstitutionalized "normal" sample, the delinquents, in contrast to previous research findings, consistently chose the delayed reward across all experimental conditions. After investigation of his subjects, Brody attributed this finding to the fact that similar research had been carried out in that institution only recently and that the subjects were no longer naive to the manipulations.

It may well be that the best way to alleviate the possible effect of these and other demand characteristics would be to enlist the

subject as an expert on his/her own behavior, both in the experimental situation and in general. Recently, Bem and Allen (1974) demonstrated the wisdom of enlisting the subject's self-knowledge to increase predictive power. They hypothesized that individuals who identified themselves as consistent on a particular trait dimension would behave more consistently cross-situationally than those who identified themselves as highly variable. Their results supported the hypothesis demonstrating consistency for some of the people some of the time. They then argued that a shift to idiographic rather than nomothetic assumptions about individual differences would improve predictive utility and that more attention should be paid to both persons and situations. This shift is supported by Jones and Nisbet (1971), who demonstrated that when explaining the behavior of others, people tend to invoke consistent personality dispositions, but when explaining their own behavior, they consider specific situations.

In summary, we agree with Mischel (1977) in arguing for a move toward more idiographic functional analyses:

The moral, for me, is that it would be wise to allow our "subjects" to slip out of their roles as passive "assesseees" or "testees" and to enroll them, at least sometimes, as active colleagues who are the best experts on themselves and are eminently qualified to participate in the development of descriptions and predictions—not to mention decisions—about themselves. (p. 249)

However, we also agree with Allport (1937) that idiographic and nomothetic methods are "overlapping and contributing to one another" (p. 22). Thus it would be unproductive to scuttle one approach in favor of the other.

Recommendation

Psychologists should take the role of the subject as expert seriously, since subjects know more than anyone else about situational influences on their own behavioral consistency. At the minimum, a postexperimental inquiry should be used as a standard experimental procedure to gather data on the operation of demand characteristics; at the maximum, the subject should be enrolled as "informant" and active participants in the exploration of his/her behaviors.

Naturalness and the Problem of External Validity

External validity concerns the extent to which the findings of a study are generalizable beyond the specific domains of that study. The relevant questions are directed at generalizability across subjects, experimental conditions, time, settings, and behaviors. Intuitively, external validity is limited to the extent that the set of conditions under which the results were obtained differ from the set of conditions to which one wants to generalize. Moreover, if generalization to real-world conditions is desired, then the closer the experimental conditions resemble real-world conditions, the greater is the potential external validity. Focusing on these assertions, the artificiality and concomitant generalizability limitations of personality-oriented research with correctional populations are viewed as a central methodological problem.

Tunnel (1977) has recently conceptualized three independent dimensions of naturalness—setting, behavior, and treatment—that he argues should be incorporated into research designs to increase generalizability of experimental results. Tunnel defined these dimensions as follows: (a) natural setting = “a context outside the lab to which a person is naturally exposed” (p. 427); (b) natural behavior = “one that is not established or maintained for the sole or primary purpose of conducting research; the behavior is part of the person’s existing repertoire” (p. 426); and (c) natural treatment = “a natural, discrete event, temporally bounded, that would have occurred without the researcher’s presence” (p. 427).

Even though research with prisoners has quite often been conducted in natural settings, Tunnel’s (1977) natural behavior and natural treatment dimensions have rarely been used in research designs. For example, of the 28 personality discrimination studies listed in Table 1, only 3 used natural behaviors as dependent measures, and none used natural treatments as independent measures. Some of the most frequently used experimental tasks include answering hypothetical questions about delaying gratification, estimating when or if future events will occur, and responding

to true-false or agree-disagree personality items. Clearly, in these tasks, neither behaviors nor treatment bear much resemblance to real-life conditions. As Mischel (1977) so aptly put it:

In the conditions of real life, the psychological “stimuli” that people encounter are neither questionnaire items, nor experimental instructions, nor inanimate events, but involve people and reciprocal relationships. (p. 248)

As a consequence of ignoring these naturalistic dimensions, the results of correctional population research are severely limited in their generalizability across behaviors and to real-world situations. Again, Mischel’s (1977) comment accurately reflects our position:

The future of personality measurement will be brighter if we can move beyond our favorite pencil-and-paper and laboratory measures to include direct observation as well as unobtrusive nonreactive measures to study lives where they are really lived and not merely where the researcher finds it convenient to look at them. (p. 248)

An article recently reviewed for *JCCP* illustrates the artificiality problem and the concomitant difficulty of generalizing across experimental conditions. The goal of the research was to elucidate components of modeling techniques and juvenile offender types potentially important in the design of treatment programs. As independent variables, two offender types (immature inadequate and socialized subcultural) and two model status dimensions (peer and staff) were studied, with imitation of self-reward criteria on a pursuit rotor task as the dependent variable. Consistent with the predictions, interaction effects were obtained in which offender types were found to be differentially susceptible to status of model influences. The authors concluded that “the results of this present study have confirmed the efficacy of the application of modeling techniques to the treatment of juvenile offenders.” Although this study was relatively free from internal validity problems, the authors’ conclusion seemed unjustifiable from the standpoint of external validity. Given that a Model Status \times Offender Type interaction was demonstrated within the microculture of this research, the potential importance of these influences to the treatment process bring into focus questions of increased

complexity. For example, the nature of Model Status \times Offender Type interactions may be quite dependent on broader social contextual influence in the natural environments of juvenile offenders. Certainly a particular setting (e.g., a correctional facility) may have considerable influence on what type of offender will imitate what type of model. Even though it is recognized that this criticism is rather pervasive and certainly not unique to this specific study, the authors provided no indication of an awareness of the complex nature of these issues.

A second external validity problem highlighted by this study centered on the choice of dependent measures. The imitation of self-reward criteria on a pursuit rotor task is quite distant from treatment goals relevant to juvenile offenders. Yet the investigators, as is often the case, suggested the extension of their method to treatment on the basis of the experimental results. Even with a more face-valid dependent measure (e.g., a treatment-relevant activity such as an increase in positive peer interactions), demonstrated generalizability across situations should be a goal.

Psychological research with correctional populations has unfortunately concentrated on artificial rather than naturalistic paradigms and measures. As a result, external validity issues have been largely neglected. As with most psychological investigations, the focus has been on internal validity issues. This underscores the internal versus external validity tradeoff in which more restrictive controls to deal with internal validity problems have reduced generalizability and increased external validity problems. Since the ultimate aim of research with correctional populations is generalizability to natural behaviors and situations, more attention should be paid to external validity issues even if it means initial loss of confidence in experimentally derived relationships. To be able to record accurately all responses in a pursuit rotor task provides us with little or no information regarding naturally occurring behavior. A shift in focus to more natural behaviors and treatments should also function as a catalyst for the development of improved methods for dealing with internal validity problems under conditions of naturalness.

Recommendation

In an effort to increase external validity, psychologists should incorporate both natural treatments and natural behaviors, as well as natural settings, into research designs. The use of direct observation in natural settings and the concomitant search for and use of nonreactive, unobtrusive measures should be encouraged.

Recidivism: A Measure in Need of Refinement

Although there has been much written in the criminology/sociology literature (e.g., Adams, 1974; Empey & Erickson, 1972; Kirby, 1954; Lerman, 1968) regarding problems inherent in measures of recidivism (an index of renewed criminal behavior following contact with the criminal justice system), we were unable to locate any discussion of the limitations of this measure in a psychological journal. Yet, recidivism, defined in its most usual form as *reincarceration following release from a correctional institution*, was used as both an independent variable in several of the personality discrimination studies and a dependent measure in the adjustment prediction and treatment evaluation studies. In the former, subjects were classified as recidivists or nonrecidivists, after which their performance on various dependent measures of personality (obtained during their previous incarceration) was assessed in an effort to determine which measures discriminated between the groups. In the latter types of studies, a host of demographic and personality variables were used as predictors of recidivism. There was, however, no indication that the investigators had any misgivings about or were concerned with the methodological problems of the recidivism measure itself. The following is a brief discussion of several issues that should concern psychological researchers who use this measure.

A major problem for recidivism measures in both types of studies is the criminal behavior/system discretion confound. In essence, recidivism, however defined, involves discretionary judgments of criminal justice system personnel that cannot be extricated from the

criminal behavior dimension that this measure is ideally designed to tap. From the decision to arrest by the police to the decision to reincarcerate by the judiciary or parole official, several discretionary judgments are made. At the point of reincarceration, the summative impact of these judgments maximizes the likelihood that differential biases have operated in determining who becomes a recidivist. Some offenders (e.g., nonwhite lower-class urban youth) may be arrested and returned to a correctional facility for relatively minor infractions, whereas others (e.g., white middle-class suburban youth) may commit the same or more serious crimes and remain out on parole. Moreover, although recidivism rates are sensitive to policy shifts at all levels, the sensitivity increases the further one becomes entangled in the criminal justice system process, with the point of reincarceration allowing for the maximum policy and administrative impact. Sellin (1962), a well-known criminologist, has commented that

the difficulty with statistics drawn from later stages in the administrative process is that they may show changes or fluctuations which are not due to changes in criminality but to variations in the policies or the efficiencies of administrative agencies. (p. 64)

One of the best examples of problems engendered by the criminal behavior/system discretion confound comes from the California Youth Authority's investigation of the community treatment program (Warren, Neto, Palmer, & Turner, 1966). First-commitment youths were randomly assigned either to experimental services in their own communities or to a control group situation that involved residence in an institution away from home. The results indicated that in general, a significantly higher percentage of control than experimental youths had engaged in parole violations (e.g., parole was officially revoked, recommitment occurred, or unfavorable discharge from the Youth Authority was given).

Although these results may have supported the contention that the community-based services were superior, Lerman's (1968) reanalysis of the data suggested that the parole violation rates were quite misleading about the behavior of the two groups. For example, despite the higher parole violation rates for the control youths, the experimentals engaged

in more known delinquent offenses per boy than did the controls. Moreover, a consideration of seriousness levels revealed that the experimentals exhibited higher delinquent behavior rates for low- and medium-seriousness offenses, with both groups about equal with regard to high-seriousness offenses. This finding, however, was confounded by evidence that the parole officers of the experimental boys were much more likely to know about their boys' offenses than the parole officers of the controls. Thus, the delinquent behavioral output may have been the same for the two groups, but the rate of being noticed was significantly higher for the experimental boys (Lerman, 1968) and the rate of reincarceration was higher for the controls. The experimental youths thus had lower parole violation rates but higher rates of recorded delinquent offenses.

This apparent, albeit spurious, contradiction can be explained in terms of differential reactions of the experimental and control organizations to recorded offenses. Although the parole officers of the experimental boys were much more likely to notice offenses, they were also much *less* likely to handle these cases via the parole violation method except with high-seriousness offenses. The lower parole violation rates obtained by the experimental group may therefore be due to their parole officers' disinclination to handle medium- and low-seriousness offenses by parole violation. Thus, the measure of recidivism may actually be telling us more about the behavior of the parole officers than that of the boys.

As elucidated in this example, the policies (and concomitant process) for both detection and handling of offenses may differ across specific organizations and with regard to particular offenders. This difficulty combined with the necessarily judgmental nature of these tasks may engender serious problems for studies that depend on recidivism measures.

The criminal behavior/system discretion confound can also be examined from the perspective of Type I and Type II errors and their varying probabilities throughout the criminal justice system process. Although it is unfortunate for researchers concerned with the reliability of recidivism data, individuals are understandably reluctant to admit when

they commit a crime. Therefore, recidivism is known only when a person is arrested, convicted, sentenced, and/or institutionalized. Throughout this process of formal contact with the criminal justice system, both kinds of classification errors are possible. A Type I error, or false positive, occurs when a person is classified as a recidivist when he/she did not, in fact, engage in criminal behavior. A Type II error, or false negative, occurs when a person is classified as a nonrecidivist when he/she did, in fact, commit another offense following release from prison. The relative probability of each error type will vary with the stage of the criminal justice system process. At the earliest point in the process—the point of rearrest by the police—there is a much greater probability of Type I errors than at later stages. For example, when the process reaches reincarceration, Type I errors are minimized by the abundance of legal safeguards along the way (unless the person is still on parole and therefore can often be reincarcerated without any judicial review). These safeguards are, of course, designed to prevent a person from erroneously being sent back to prison. Although the probability of Type I errors decreases as one moves further into the administrative process, the probability of Type II errors correspondingly increases. Thus, the Type II error presents the major problem for studies that define recidivism as reincarceration.

Type II errors present at least two kinds of relevant problems. In each case the difficulty lies with the determination of the nonrecidivist group. First, due to the impossibility of detecting every offender and the inconsistencies of crime detection systems, many persons classified as nonrecidivists may, in fact, have committed a crime. In the evaluation of the community treatment program, for example, the fact that the experimental boys had more recorded offenses than the controls may have been due to a greater likelihood of being noticed by their parole officers rather than to any real difference in delinquent behavioral output. Detection system differences rather than behavioral differences may thus play a role in the recidivist-nonrecidivist classification process. Second, with recidivism defined as reincarceration, all parole viola-

tions and other forms of criminal justice system contact short of reincarceration may still result in a person being classified as a nonrecidivist. Fortunately, most of the studies examined defined a nonrecidivist as a person having *no contact* with the criminal justice system. A problem still remains, however. Although the no-contact and reincarceration criteria for nonrecidivist and recidivist may assure maximum differences between groups (and maximum differences in criminal justice system reentanglement), all gradations of law-violative behavior and criminal justice system contact in between these extremes is ignored. Some investigators (e.g., Roberts, Erikson, Riddle, & Bacon, 1974) improved their methodology by including all of these gradations into a third, *some contact*, group. Finer differentiations (e.g., by frequency and type of offense) with more than three groups could yield still more accurate and complete information.

Two additional problems, both related to institutional bookkeeping, warrant attention. First, individuals are often counted as nonrecidivists who end up in other institutional programs (e.g., mental hospitals), die, or move out of state where they may engage in criminal behavior and even be reincarcerated. The point is that these individuals, because they have not been reincarcerated in a correctional facility in the same state, are often classified as nonrecidivist. Clearly this designation is erroneous. Second, although most investigators suggested that they used no contact with the criminal justice system as a criterion for nonrecidivism classification, in no study was there any indication of how this information was gathered. The problem is that most investigators usually consult only one source to gain this information under the assumption that there is a coordinated record keeping system between all aspects of the criminal justice apparatus within a given state. This is a faulty assumption. Not only does such a coordinated system usually not exist, but also depending on which source of information one uses (e.g., police records, correctional department files, parole officers reports, court records), one is likely to find different numbers and types of recidivism information on any given individual. Thus, dif-

ferent conclusions about the extent and nature of recidivism may vary depending on source of data. Although these problems may be more serious when recidivism is used as a measure of treatment program success, researchers who use this measure in other types of studies should be aware of the fact that the measure is not as straightforward and internally valid as it is generally assumed.

Recommendation

Recidivism should be operationally defined whenever it is used, and source of data should be provided. When used as a measure of post-institutional adjustment, recidivism should be supplemented by other measures of adjustment in the areas of education, employment, and family life. When possible, recidivism measures should be based on multiple gradations of such factors as extent of contact with the criminal justice system, frequency of law-violative behavior, and type and seriousness of offense.

Ethics of Research with Correctional Populations

This is an area that has attracted much professional attention recently but one that some investigators may not wish to consider as a methodological issue. We, however, consider it to be so integrally related that a brief discussion is warranted within the present context.

The National Commission for the Protection of Human Subjects in Biomedical and Behavioral Research (1977) has recently provided recommendations regarding prison research that have considerable merit. The Commission recognized three broad categories:

1. Research conducted with the goal of improving institutional and program effectiveness, which includes psychological treatments having "the intent or reasonable probability of improving the health or well-being of the individual prisoner" (p. 3080);

2. Research inherently related to prisoners but not having a goal of benefiting them (e.g., investigations of prisoner personality) or "the possible causes, effects and processes of incarceration and studies of prisons as in-

stitutional structures or of prisoners as incarcerated persons" (p. 3080); and

3. Research using prisoners as subjects because they are available rather than because of their status as prisoners (e.g., psychopharmaceutical testing).

The Commission recommended that a human subjects review committee, composed of individuals of diverse racial and cultural backgrounds, including prisoners, prisoner advocates, clergy, community representatives, behavioral scientists, and medical personnel, should approve *all* research. This committee would consider the risks involved in the research, the provisions for obtaining informed consent, and safeguards to protect confidentiality and other concerns. Furthermore, parole boards could not take into account prisoners' participation in research. Research in the second category, that is, nonbeneficial but related to prisoners, must additionally "present minimal or no risk and no more than mere inconvenience to the subjects" (National Commission for the Protection, 1977, p. 3080). Finally, research on prisoners because of their availability could only be conducted if three additional requirements were met: (a) The research must fill an "important social and scientific need," (b) it must "satisfy conditions of equity," and (c) it must be distinguished by "a high degree of voluntariness" on the part of the prisoner.

These recommendations deserve close attention and adherence. As Brodsky (Note 2) recently stated in his report to the APA Task Force on Psychology and the Criminal Justice System:

In spite of the fact that there may be some observational and nonreactive investigations which would seem to have minimal impact—such as questionnaire studies—the potential for both misuse and harm to individuals exists in any study. In these as well as the more active manipulations of treatment conditions or offenders, it is important that consent forms, institutional reviews and other elements of protection for human subjects be included. (p. 57)

Recommendation

Some acknowledgment that ethical safeguards have been used (e.g., informed consent was obtained) should be included in the Method section of all research submitted for publication in APA journals.

Conclusion

In concluding this article it is perhaps worth stating that the issues discussed are neither exhaustive of the methodological problems confronting psychologists doing research with correctional populations nor are they complete discussions in and of themselves. Moreover, the emphasis on personality discrimination research may provide the reader with a distorted view of the type of research that is conducted with correctional populations. Although this may be true, it is certainly no distortion to suggest that this is the predominant type of research that is published in *JCCP* and *JAP*. Finally, we do not expect that all of the issues discussed can be satisfactorily resolved in any single research project. Nevertheless, we firmly believe that most of these issues have received little sustained attention in past psychological research with correctional populations and that this state of affairs should not continue.

Methodological Errors in Marital and Child Treatment Research

K. Daniel O'Leary and Hillary Turkewitz
State University of New York at Stony Brook

Common methodological errors in child and marital treatment research are discussed, and suggestions are made to help investigators avoid such errors. The following areas are covered: selection of subjects and therapists, scope and source of dependent measures, treatment specification, experimental design, and data analysis and interpretation. Some of the most salient errors include (a) unsubstantiated diagnoses or client labels; (b) very few therapists per treatment condition; (c) restricted outcome criteria and the lack of reliable, valid dependent measures; (d) failure to provide treatment manuals and to check empirically whether the treatments were actually implemented; and (e) experimental designs that fail to address issues such as maturation, expectation, nonspecific relationship factors, and practical significance.

Our purpose is to discuss methodological problems that are common to most child and marital treatment research. Child and marital therapy are addressed as separate activities, although we recognize that childhood disorders are often influenced by marital discord and vice versa. That is, even though the problems of children and marriage are often not independent, we are reviewing the difficulties in research when either the child or the marital interaction is the focus of treatment. Such specific programs have proven successful in treating marital (Gurman & Kniskern, 1978) and childhood problems (K. D. O'Leary & Wilson, 1975). We recognize that individuals with other treatment orientations might view child and marital problems only within a family context and would treat the whole family—children, parents, and sometimes grandparents—simultaneously. Family therapy research will not be specifically addressed here; readers interested in this methodology should consult Wells, Dilkes, and Burckhardt (1976).

Marital discord has highly diverse etiologies, and distressed couples present a wide variety of problems including role conflicts, jealousy, individual pathology, physical abuse, and sexual dissatisfaction. Despite the varied presenting problems, most marital researchers and therapists have the commonly accepted goals of enhancing communication (D. H. Olson, 1970) and increasing satisfaction. The outcome research involving these general goals will be the focus of this article. Those interested in the research methodology of treatment for specific sexual dysfunctions should consult LoPiccolo (1978).

Two of the most commonly diagnosed childhood problems are conduct disorders (unsocialized aggressive reaction) and hyperkinesis (Cerreto & Tuma, 1977), and we will illustrate methodological errors in child treatment research from these areas. Both problems are the result of complex psychological, social, and biological factors, and the goals of treatment are multiple, including increases in academic productivity, frustration tolerance, attention span, positive parent-child interactions, and self-esteem. Consequently, the childhood problems covered represent areas of concern to most child treatment researchers. For those interested in other specific childhood problems, such as autism, enuresis,

We are especially appreciative of the editorial comments of S. G. O'Leary, D. Gelfand, and A. Gurman. Requests for reprints should be sent to K. Daniel O'Leary, Department of Psychology, State University of New York, Stony Brook, New York 11794.

adolescent suicide, and delinquency, *Annual Progress in Child Psychiatry and Child Development* (Chess & Thomas, 1977) and *Handbook of Treatment of Mental Disorders in Childhood and Adolescence* (Wolman, Egan, & Ross, 1978) are recommended as sources of discussions on substantive and methodological problems.

We will address common methodological problems by noting frequent errors of omission and commission and by making suggestions that can help investigators avoid such errors. The methodological errors will be discussed in the order of their occurrence as one reads a manuscript (American Psychological Association, 1974). More specifically, we will discuss (a) subjects, (b) therapists, (c) dependent measures, (d) treatment specification, (e) experimental design, and (f) data analysis and interpretation of results. The suggestions are offered as guidelines, but it is recognized that in outcome research with child and marital populations, meeting all of the suggested recommendations may be impossible. The extent to which they are met, however, will clearly increase both the internal and external validity of the research.

Subjects

Small Sample Size

Controlled research in child, and particularly marital, therapy is plagued by the problem of small subject samples. Enough subjects should be included in each experimental group to enable an investigator to detect outcome differences of practical and/or theoretical import. If one desires a guaranteed degree of power, the necessary sample size can be determined empirically by using prior estimates of treatment effectiveness (Winer, 1971). In any case, as Hartmann, Roper, and Gelfand (1977) noted, one must consider subject attrition, since the sample size of concern is the terminal sample, that is, the number of individuals who complete *all* phases of a study from pretreatment to follow-up. Obtaining significant results with a small sample may be a compelling testimony to treatment effects, since small *ns* decrease power or the ability to detect treatment differences. How-

ever, the smaller the sample, the greater the probability of sampling error and artifacts that would limit the generalizability of the findings.

YAVIS Samples

Williams (1956) coined the acronym YAVIS (young, attractive, verbal, intelligent, successful) in his discussion of the 'typical psychotherapy patient. This problem of restricted patient populations is particularly salient in the controlled research on marital therapy. Almost all of the published studies contain young, well-educated, middle-class couples. Because age and/or number of years married can affect the outcome of different approaches to marital therapy (Turkewitz & O'Leary, Note 1), a sample should be selected that includes a wide age range or one's conclusions must be restricted to the particular age group involved in the study. Further research is necessary to evaluate marital treatment programs for both older clients and clients from lower socioeconomic backgrounds.

Unspecified Subject Characteristics

A very common error of omission in the presentation of research on child and marital therapy is inadequate sample description. In addition to age, educational level, occupation, socioeconomic status, and information regarding previous therapy, authors should specify the fee paid, if any, for treatment in the research program. In marital therapy outcome studies, the mean and range of years married, the number of children, and the number of previous marriages should also be reported. In child research, it is advisable to provide information on the parents' marital status and the involvement of mothers and/or fathers in treatment. Depending on the particular child problem under study, a thorough assessment and description of the sample may involve a measure of intellectual functioning, academic performance, or marital satisfaction of the parents. A complete description of subject characteristics is necessary so that other researchers can attempt replications of the research and so that practicing clinicians can judge if the treatment

program described is likely to have similar effects for the population with whom they are working.

Unsubstantiated Labels and Diagnoses

In addition to specifying demographic characteristics, researchers executing outcome studies generally describe the subjects as having a particular clinical problem, for example, marital distress, adjustment reaction of childhood, or hyperactivity. However, outcome research is often hampered by very general definitions of these labels. To allow for generalizations regarding the treatment and replications of studies, specific data substantiating the diagnoses must be provided. For example, in marital research, couples referred by divorce courts are probably more severely distressed than those referred by clergy. Degree of distress could also depend on geographical location and community sanctions regarding divorce. Obtaining a numerical rating of distress from a valid assessment instrument that has normative data provides a description of the sample that can be understood by other professionals and increases the reliability of the diagnosis of marital distress. The Locke-Wallace Marriage Relationship Inventory (Kimmel & Van der Veen, 1974; Locke & Wallace, 1959) is a useful questionnaire for these purposes, as discriminant validity (Locke & Wallace, 1959), construct validity (Weiss, Hops, & Patterson, 1973), and test-retest reliability (Kimmel & Van der Veen, 1974) have been demonstrated for various forms of this inventory.

Similarly, the need for specific, defined criteria is particularly salient in the research on hyperactivity. Children may be diagnosed as hyperactive by a pediatrician, clinical psychologist, psychiatrist, or school psychologist. Additionally, children may receive the label because they are taking Ritalin, have been referred by a teacher, or have parents who sought help in handling them at home. These varying sources of labels yield highly heterogeneous groups of children described as hyperactive. In this regard, the prevalence rates of hyperactivity range from 4% to 20% of elementary school samples (Ross & Ross, 1977). Even though teachers are probably

the best information source regarding a child's activity level, caution should be observed in basing a diagnosis of hyperactivity on a single teacher's referral. Teachers occasionally inflate their assessment of a child's problems because they want to obtain consultation from the researcher (S. O'Leary, Note 2). Further, mental health practitioners may not be able to diagnose hyperactivity reliably (Kenny et al., 1971). A recommended assessment measure for hyperactive children is the Conners Teacher Rating Scale (Conners, 1969). However, such a measure should be supplemented by parent ratings (Routh, Schroeder, & Otuama, 1974). The general principle is that labeling or diagnosing the subject population requires well-validated, reliable measures to substantiate the descriptive label.

Inadequate and Unspecified Selection Process

An investigator conducting outcome research should define the problem under study and include only those subjects who meet a priori criteria. The use of a priori criteria increases the likelihood that the sample obtained has clinically significant problems and will be comparable to those in other investigations. (This argument assumes that some other investigators also use commonly accepted criteria for clinical problems.)

We recognize that it is often difficult to obtain a sufficiently large sample if one uses stringent a priori criteria regarding severity of the problem. If this is not possible, a more general criterion such as referral by a teacher, parent, pediatrician, mental health clinic, or divorce court should be accompanied by a specific description of the referral process and descriptive measures like the ones discussed in the previous section. If more than one referral source is used, the percentage of subjects obtained from each different source should be noted, as different sources can produce clinically different samples, for example, teacher versus pediatrician and clinic versus court referrals.

In addition to a severity criterion, many researchers exclude clients who would not be appropriate for the treatment under study. Examples of these exclusionary criteria in

short-term marital therapy are evidence of severe psychopathology in either spouse (e.g., psychosis or chronic alcoholism), concurrent therapy, spouses living separately, and the refusal of either spouse to cooperate in the treatment program. In child treatment programs, exclusion has been based on neurological impairment, childhood psychosis, inability of both parents to attend therapy sessions, severe marital discord, or uncooperative teachers. Although these exclusionary criteria may be valid for certain treatments, they are often not specified. For example, researchers rarely state how they determined the presence of neurological involvement or severe psychopathology. As excluding subjects with these problems limits claims of generalizability of the results, it is important to describe the decision-making process and specify the percentage of potential subjects who were excluded.

Therapists

Small Therapist Samples

One of the most common methodological errors made in marital and child outcome research is that the number of therapists involved is too small to allow for appropriate generalizations regarding treatment. Therapist factors have been repeatedly shown to influence outcome in family therapy (Gurman & Kniskern, 1978), and it is very likely that these factors also have an impact on child and marital treatment. Given the importance of therapist variables, it is necessary to have as many therapists as practically feasible so that one can study whether one's treatment program can be successfully implemented by therapists of varying styles. Keeping in consideration the need for training and close supervision in studies of particular treatment programs, a minimum of 3-4 therapists per experimental condition is strongly advised. When therapist factors become a major focus of the research, the number of therapists should be even greater.

Bias Introduced by Motivational Factors

Teacher incentives. In child treatment research, motivational factors need to be con-

sidered when teachers are asked to implement therapeutic programs in their classrooms. If a teacher receives graduate credits, free time, additional classroom materials, or teaching assistants for conducting an intervention, these potential reinforcers can positively bias the consistency and quality of the teacher's efforts. We would not advise against using such incentives, but it should be noted that clinicians in nonresearch settings cannot offer the teacher incentives and consequently might not find the intervention to be as successful as it appeared in the research program.

Authors as therapists. A serious methodological problem regarding therapist selection involves the experimenter(s) as therapist(s). The emotional investment and enthusiasm of the author/therapist may increase placebo effects and spuriously inflate the success of the treatment under evaluation. These factors would hold even if there were two or three therapists, if all were authors.

Confounds Resulting from Therapist Characteristics or Theoretical Biases

The general issue of motivation and enthusiasm for a particular treatment approach becomes even more critical when two or more treatments are being compared. Many of the comparative studies in the marital and child treatment areas involve two or more therapists who implement both treatments under study. This methodology of crossing therapists with treatments has clear advantages and disadvantages. One advantage is that differential treatment outcomes can more readily be attributed to the treatments rather than to the skill of the therapists (since the therapists are the same for both treatment programs). One serious disadvantage, however, is the possibility of systematic bias if all the therapists involved have a theoretical orientation that favors one of the treatments. For example, if several behavior therapists were to execute a study comparing behavioral marital therapy with a systems approach and if these behavior therapists were to conduct both treatment programs, a bias would be introduced by greater enthusiasm for the behavioral intervention, greater knowledge of the specific behavioral procedures, and more

clinical experience in treating clients with behavioral methods.

Rather than crossing therapists with treatments, different therapists can execute each program under study. If this methodology is used, large numbers of therapists must be used to avoid confounding treatment effects and differential therapist skills. The difficulty in obtaining a sufficient number of therapists of differing orientations often led investigators to cross therapists with treatments. Because this method is frequently used, the following recommendations are made to reduce possible biases: Include therapists of varying theoretical orientations; present cogent rationales and theoretical explanations for all treatments under study; offer extensive training programs, including readings, role playing, and pilot cases; and provide close supervision. Even with these precautions, any therapist biases should be assessed and reported. For example, one can obtain the therapists' predictions regarding the effectiveness of the different approaches and their reports on how comfortable they were in conducting the treatments. The assessment and control for the biases introduced by therapist factors is important, because the small number of therapists often involved in treatment research makes it difficult, if not impossible, to study the influence of therapist characteristics statistically.

Inadequate Description of Therapists

Information should be included on the therapists' (and/or teachers') training, educational, and professional background; sex; age; previous experience with marital or child treatment; and incentives for participation (salaried vs. volunteer). In studies of marital and child therapy, the marital status of the therapists, and whether or not they have children may be of interest.

Dependent Measures

Multiple Outcome Criteria

A very serious error in child and marital treatment research is the lack of multiple outcome criteria (Johnson & Christensen,

1975). In both the child and marital areas, many investigators have relied exclusively on self-report measures. In contrast, some of the child treatment studies—especially evaluations of behavior therapy programs—have included only naturalistic observations. As self-report and observational measures both have strengths and weaknesses (K. D. O'Leary & Johnson, in press) and sometimes can lead to different conclusions (e.g., Harrell & Guernsey, 1976; Liberman, Levine, Wheeler, Sanders, & Wallace, 1976), neither data source should be considered sufficient. Each provides unique information that is necessary in any comprehensive treatment evaluation.

Some authors have argued for a tripartite assessment model including self-report, observational, and physiological measures (Lang, 1971). Such a model has been quite useful in evaluating fears and anxiety, but the model is not especially relevant to the evaluation of child and marital treatment. In child treatment, academic achievement tests, mechanical measures (such as stabilometer chairs to assess hyperactivity), and sociometric evaluations are useful adjuncts to self-report and observational measures. In marital treatment, adjunctive measures such as days absent from work, job productivity, and physical well-being could be considered.

Regardless of the type of assessment data obtained, a clinical interview is a critical and almost universal mode of assessment. However, the material collected in an interview, the meaning assigned to that material (e.g., a personality structure or a behavior reinforced by significant others), and the extent of standardization in the interview will depend on one's theoretical orientation. Under certain conditions a clinical interview can be reliable, and the interview allows for maximal flexibility in developing new hypotheses regarding a client's problem (K. D. O'Leary & Johnson, in press).

Comprehensive Assessment

In addition to the assessment modality that is used, there are two major issues to be considered when choosing dependent measures:

1. Scope of the assessment. For example in a child treatment study, possible factors

of interest include classroom academic and/or social behavior, self-esteem, a child's feelings toward his/her parents or teachers, and parent-child interactions at home. In marital therapy outcome research, one can consider assessment of individual functioning, sexual satisfaction, role conflicts, social life, expectations of and feelings toward one's spouse, and a consumer evaluation of the program.

2. Source of the data. Strupp and Hadley (1977) argued that psychotherapy outcomes should be evaluated from three different perspectives—(a) society or significant others (e.g., relatives, teachers, employers), (b) the client, and (c) the therapist. In particular, we emphasize the strong need for data from the child's perspective in evaluations of child therapy.

The choice of dependent measures and the data sources will be dictated by one's theoretical orientation and the particular questions of interest. It is beyond the scope of this article to discuss fully all of the factors that should be assessed in the study of various child or marital problems. (The reader is referred to Gurman and Kniskern, 1978, for a detailed discussion of this issue.) As self-report and observational measures are the most commonly used dependent measures in the evaluation of child and marital treatment, they will be discussed in detail.

Self-report

One of the most frequently cited problems of self-report measures is the influence of demand characteristics (e.g., cues that convey the experimental hypotheses and the implicit or explicit expectations to the clients). Demand characteristics can be minimized by keeping the specific criteria for inclusion in a treatment study unclear to the clients, by having the therapist absent when questionnaires are completed (either before or after therapy), and by taking great care not to pressure the clients to report success in order to help the therapist.

Social desirability, or the tendency to respond in a conventional, socially acceptable fashion, is also a problem that limits the utility of self-report data. For example, Edmonds (1967) found that a large percentage of

spouses answered "true" to *impossible* responses. (e.g., "There is never a moment I don't feel head over heels in love with my spouse.") It is moot whether these socially desirable responses reflect active distortions or honest tendencies of spouses to exaggerate positive qualities of their mates, and it has also been argued that a large percentage of socially desirable responses may not decrease the validity of a marital satisfaction test (Murstein & Beck, 1972). A full discussion of social desirability is not warranted here. However, when social desirability may be a critical factor (e.g., cases of child abuse), an investigator can consult the personality research literature for methods to control for it, such as transforming raw scores using a social desirability correction factor (e.g., Minnesota Multiphasic Personality Inventory) and developing special multiple-choice questionnaire formats.

A third problem of self-report measures that is often overlooked is that clients must have a certain language proficiency to complete questionnaires; and with few exceptions (e.g., Bienvenu, 1970), authors do not specify the degree of literacy required. When treating clients with limited educational backgrounds (a group much neglected in the marital research area), investigators should use a reading survey instrument to determine the language proficiency required to complete their questionnaire (e.g., Fry, 1968).

Finally, a common error is to use self-report measures that do not have established reliability and validity, which renders the degree of reported change very difficult, if not impossible, to interpret. Valid questionnaires are available in the marital area for assessing communication (e.g., Navran, 1967) and satisfaction (e.g., Locke & Wallace, 1959). For child treatment studies, there are numerous teacher and parent rating scales that have demonstrated reliability and validity (Achenbach, 1978; K. D. O'Leary & Johnson, in press; Quay, in press). On the other hand, valid self-report questionnaires that assess self-esteem and attitudes of children toward parents and school are needed (cf. Cooper-smith, 1967).

Even though all of the problems associated with self-report measures cannot be elimi-

nated, we strongly recommend their use because they are focused, convenient, and economical. Further, certain areas cannot be assessed by observational measures (e.g., perception of feelings toward one's spouse, expectations regarding marriage, attitudes of children toward teachers, and self-esteem).

Observational Measures

The problems discussed above in regard to self-report measures indicate a clear need for direct observation of the behaviors of interest. Direct, or naturalistic, observation has become a hallmark of research in behavior therapy, and certain journals will often not accept manuscripts that do not include such data (e.g., *Journal of Applied Behavior Analysis*). Direct observations usually provide less biased data than self-reports, and they can be used to obtain information not easily provided by clients (e.g., data on facial expressions or other nonverbal aspects of communication of which a spouse or parent may not be aware). Finally, the collection of audiotapes and/or videotapes allows for the possible reanalysis of data by different investigators who wish to compare and contrast treatments.

In the child treatment area, observational coding systems have been used extensively in classrooms (Kent & Foster, 1977). Classroom observations have proven reliable, valid, sensitive to treatment changes; are largely non-reactive (S. G. O'Leary & K. D. O'Leary, 1976); and are capable of distinguishing control from clinical populations (Abikoff, Gittelman-Klein, & Klein, 1977). In homes or simulated home settings, direct observations of children have also proven reliable, valid, and sensitive to treatment changes (Patterson, 1974), but sometimes they are reactive; that is, the presence of an observer in a home can alter the nature of parent-child interactions (White, 1977). The problem of reactivity is an important one that is often overlooked and may be especially problematic with adolescents when only a few observations are made (K. D. O'Leary & Johnson, in press).

Marital interaction codes have been developed that discriminate between distressed and nondistressed couples (Rausch, Barry, Hertel, & Swain, 1974; Gottman, Notarius, & Mark-

man, Note 3). However, with few exceptions, complex coding systems have not been used as pre-post dependent measures (e.g., Weiss, Hops, & Patterson, 1973). The use of such observations is strongly recommended, and several methodological issues should be considered. In marital treatment research the observational context is generally a laboratory or interview setting. Many investigators use variations of Strodbeck's revealed difference technique (Strodbeck, 1951), in which the experimenter identifies differences of opinion between the spouses and then asks them to resolve these differences and reach mutually agreed-on conclusions. Typically, the couple is left alone when discussing the conflicts, and their interaction is videotaped or audiotaped. When using this procedure, discussions may occur that evoke very hostile feelings. Thus, it may be ill-advised to assess certain populations (e.g., physically violent couples) in this manner. In all cases, the investigator should conduct at least a brief clinical interview following the task to insure that the spouses do not leave the assessment interview angrier with each other than when they arrived.

The content of the conflicts discussed may have a critical influence on the data obtained. For example, some evidence indicates that with older couples a high degree of induced conflict is necessary to discriminate the communication patterns of distressed and nondistressed couples (Gottman, Notarius, Gonso, & Markman, 1976). In the Gottman et al. study, the difference between the high and low conflict situations involved the degree to which the topic discussed was relevant to the marital relationship. One implication of this finding is that topics relevant to the couples' problems produce more realistic samples of communication.

A method used to insure a highly relevant discussion has been to ask the couples to discuss their own marital problems. However, we feel that this procedure has a serious methodological problem in that a change in the interactions may reflect either an amelioration in the particular presenting complaints or an alteration in the general communication style of the couple. Presumably, general

changes in communication and problem-solving skills should be measured on topics relevant to, but not identical with, the couple's presenting problems if predictions are to be made about how the couple will handle conflicts that arise in the future.

One additional methodological issue in the marital area involves selecting the kinds of behaviors to observe and the means to assess them. Both the affective and content domains of communication should be assessed to discriminate between distressed and nondistressed couples (Gottman et al., 1976). Although it is not clear that videotapes offer incremental validity over audiotapes, the affective quality of an exchange ought to be more easily assessed on videotapes (e.g., sneers, eye contact, body position). However, since video recordings are costly, potentially reactive, and unavailable in most nonresearch clinics, reliable, discriminating codes for rating audiotapes should be developed.

At present, observational methodology in the child treatment area, particularly in classrooms, is more sophisticated than that in marital therapy research. Further development of behavioral codes of marital interactions and parent-child interactions in the home is mandated. Observational methodology is costly and time-consuming, but obtaining independent observations that supplement self-report data is usually crucial.

Treatment Specification

Therapy Manuals

Failure to specify therapeutic procedures in detail is one of the most common and yet most serious problems in psychotherapy research. This error is largely an error of omission, and to rectify the problem some journal editors (e.g., *Cognitive Therapy and Research*, *Journal of Applied Behavior Analysis*) have recently required that treatment manuals be made available for interested readers through the author, the National Auxiliary Publications Service, or some other central information source. Without such manuals or other training materials (e.g., video or audio cassettes), replication of treatment studies is almost impossible.

Training Programs

In addition to the description of the actual treatment, a manuscript should include the following information on the therapists' preparation: the length and type of training, that is, pilot cases, role playing, reviewing tapes, and books, manuals, and other reading materials used. The amount and frequency of therapy supervision should also be specified. Since complete specification of the training program would be impossible in most journals, details regarding the training programs should be explicated in therapy manuals.

Assessment of the Independent Variable(s)

To state unequivocally that a treatment is effective, some measure that the treatment was actually implemented must be obtained. In psychological research, several levels of analysis can be used to assess the independent variable. On one level, an investigator can determine whether the therapists acted in accord with the therapeutic regimen. At a second level, with regard to certain types of therapy (e.g., behavior therapy), a determination can be made of whether the clients actually implemented the procedures recommended by the therapists. For example, in a communication program for parents and children, one should assess whether the therapists gave the appropriate suggestions as outlined in the therapy manual. It can also be determined whether or not the parents followed the designated communication exercises with their children at home.

Checks on the independent variables in treatment research with children and marital partners are seldom reported or are incomplete. Both therapists' and clients' self-reports, as well as observations of therapy programs or analyses of therapy tapes, are strongly advocated. Having a detailed behavioral assessment of the independent treatment variables prompts investigators to provide adequate treatment descriptions, including the percentage of time therapists spent in various treatment activities. Most importantly, when comparisons between different treatment programs are made, an investigator should provide reliable, objective data to document the

actual procedural differences that distinguished the various treatment groups.

Experimental Design

Aspects of therapist-client interactions that should be controlled for include attention to a client's problem, expectations about therapeutic outcome, and other nonspecific relationship factors. Traditionally, solutions for such problems have been placebo or attentional control groups. We consider placebo groups to be ethically and methodologically problematic, and a number of alternatives have been suggested to control for therapist attention and client expectations (K. D. O'Leary & Borkovec, in press). A few of these choices are (a) the use of the best available alternatives (Jacobson & Baucom, Note 4), that is, comparing one form of treatment with another commonly accepted treatment for a particular problem; (b) component control comparisons in which procedural elements from a total treatment package are evaluated; (c) evaluation of the same treatment program under two different conditions—a neutral expectancy control group that receives a neutral expectation set and a second group that receives usual or exaggerated positive expectation sets; and (d) counterdemand manipulations in which clients are told that they should not expect improvement until after a fixed number of sessions. A full discussion of controls for expectations, therapist attention, and relationship factors is clearly beyond the scope of this article, but such factors must be addressed by any serious researcher.

For problems that change with maturation or remit spontaneously, waiting list controls for limited periods may be especially useful. Clearly, knowing whether an intervention is more effective than none at all is absolutely necessary. In child treatment evaluations, maturational controls are critical (Kent, 1976), and although many people would think that marital cases are generally unlikely to change during short periods without treatment (Gurman, 1975), the inclusion of waiting list control groups can result in tempered claims regarding the effectiveness of an intervention (K. D. O'Leary & Turkewitz, 1978). When ethical concerns do not allow for inclusion of a standard waiting list control

group, the clients on the waiting list can be monitored, and those who evidence deterioration can be placed in the treatment group (Stuart, 1973).

When comparing different treatment programs, some assessment should be made regarding the clients' acceptance of the therapeutic rationale (Kazdin & Wilcoxon, 1976). In addition, clients should be asked to evaluate the therapists as well as the therapeutic procedures (Kazdin, 1977; Kent & O'Leary, 1976; Wolf, 1978).

Single-subject or within-subject designs have been used by both child and marital researchers, and they have been especially useful in evaluating the effectiveness of treatment procedures when (a) the effect can ethically be reversed (reversal designs) or (b) generalization of effects across behaviors is small (multiple baseline designs). When either of these conditions is unlikely, group designs should be used. (For a full discussion of single subject methodology, consult Hersen & Barlow, 1976.)

In addition to deciding on adequate control groups and research designs, plans should be made to collect follow-up data to determine whether the treatment effects persist when the natural environment is not reprogrammed by the therapist. An assessment of the posttreatment environment is advisable—especially with children—to ascertain the conditions under which behavior is or is not maintained (Bijou, 1974).

Data Analysis and Interpretation

A common error in analyzing data from dyadic interactions in the child and marital areas is to include both partners from the dyad in the degrees of freedom. Since the members of the dyad influence one another, they should not be regarded as independent units in analyses of variance. For example, in examining the simple pre-post effects of an intervention on 10 couples, analyses using data from individual subjects should be partitioned as follows: pre-post, male versus female, the interaction between male-female and pre-post, and couple differences. Alternatively, the average of the husband's and wife's scores could be treated as a single unit.

If a therapist conducts group therapy, as

is often the case in marital research (Gurman & Kniskern, 1978), generalizations about therapeutic effects must be limited to a group context and the number and types of therapist(s) used. Further, the nonindependence of subjects must be considered in determining the degrees of freedom for testing group effects. As a general rule, the number of therapy groups in each experimental condition should be large enough to detect differences that cannot be attributed to idiosyncratic group characteristics.

If several dependent measures are used and the correlations between the measures are high, a multivariate analysis of variance that takes the intercorrelations into account should be considered (C. L. Olson, 1976).

Practicing clinicians who are the major consumers of clinical research are concerned about individual variability (range and standard deviation) in response to treatment. Consequently, estimates of the strength of association (omega-squared) should be reported wherever possible to allow the clinician to ascertain the impact of the treatment (Hays, 1963). That is, it is useful to know the percentage of variance in a dependent measure accounted for by the treatment.

Subject attrition and incomplete data can present serious problems in interpretation. In a review of psychotherapy literature, Baekeland and Lundwall (1975) found that clients who dropped out of treatment were more likely to be from lower socioeconomic groups and to have little affiliation with others. As such factors may relate to outcome, it is essential to report the percentage of dropouts. Additionally, one should attempt to obtain posttermination data from dropouts; we have found that some clients are willing to complete the assessment even if they are unwilling to continue in therapy. There are occasions when clients participate in the entire therapy program but do not complete the posttreatment or follow-up assessment materials. In an evaluation of a child clinic, Olmanns, Broderick, and O'Leary (1977) found a significant relationship between difficulty in obtaining outcome data and responsiveness to treatment. Thus, both therapy dropouts and missing data points should be considered as potential sources of positive bias.

Conclusion

Salient methodological errors in conducting child and marital treatment research include inadequate client and therapist selection and description, unsubstantiated labels and diagnoses, lack of multiple outcome criteria, use of dependent measures of unspecified reliability and validity, and failure to provide treatment manuals and to check whether the specific treatments were in fact implemented. Experimental design issues are complex and relate to the substantive questions of interest. Very common problems, however, involve the need to control for expectation, therapist attention, and relationship factors, and the failure to conduct follow-up evaluations. Finally, common errors in data analysis and interpretation have been noted. Throughout the text suggestions have been made to help minimize the methodological errors discussed.

Psychopathology of Childhood: Research Problems and Issues

Thomas M. Achenbach
National Institute of Mental Health
Bethesda, Maryland

It is argued that research on child psychopathology would benefit from reducing the influence of adult treatment models and from applying a developmental perspective to clinical research on children. Specific methodological problems are discussed, including the assessment of subject characteristics; the use of replicable and generalizable diagnostic classifications; the effects of situational specificity and developmental variance on measures of children's behavior; the need to avoid pathological biases in judging children; relationships among correlation, causation, and prediction in a developmental context; problems in measuring change; and the effects of age, cohort, and time of measurement, as well as fallacies in drawing longitudinal conclusions from cross-sectional data. Outstanding research needs are also identified, including the need to devise and use well-standardized measures; the need to evaluate interactions between subject and treatment variables in outcome research; the need for long-term follow-ups of children identified as being at risk; the need for cumulative programmatic research; and the need to link research more closely to service systems.

Research on child psychopathology has traditionally been treated like a stepchild for whom no one assumes full responsibility. Despite clinical emphasis on the childhood roots of adult disorders, psychopathology has been studied far more intensively in adults than in children. Furthermore, research on psychopathology in children has been unduly shaped by a mental health system in which clients must adopt a patientlike role. This system may not be entirely unjustified for adults, but it engenders assumptions that are certainly inappropriate for children.

First, children rarely have realistic conceptions of psychopathology and mental health services. Second, both the judgment that a child needs help and the initiative required

to obtain it originate with adults rather than with the child. Third, children have much less freedom to alter their circumstances than do adults, and adult-centered views of treatment as primarily a relationship between therapist and patient neglect children's overwhelming dependence on their families. Fourth, unlike adults who have reached plateaus in their social, educational, cognitive, and physical growth, children must be viewed in relation to their progress along these dimensions. Rather than judging clients' problems in terms of interference with current capabilities—as may be appropriate with adults—it is necessary to judge children's problems in terms of their interference with future development. Unless children can progress in knowledge, skills, and ways of relating to others, they are unlikely to achieve a successful adaptation in the long run, no matter how satisfactory an outcome may appear in the short run.

To help troubled children, we need a far greater investment of resources, energy, and brain power in objectively assessing their needs and in developing and evaluating sys-

The author is grateful to Craig Edelbrock, Gale Inoff, and John Weisz for their critical readings of the manuscript.

tematic approaches to meeting these needs. Despite a flood of rhetoric and legislation on behalf of children, there is little evidence of cumulative progress in alleviating children's mental health problems. In my view, it is the responsibility of mental health professionals not only to advocate funds and programs for children but to begin demonstrating more accountability for the services rendered. The lack of evidence for the efficacy of most mental health services to children (cf. Achenbach, 1974; Levitt, 1971; Shepherd, Oppenheim, & Mitchell, 1971) behooves mental health professionals to assume greater initiative in determining how disturbed children can in fact be helped. Reform is vitally needed to improve the mental health services available to children. However, meaningful reforms can only originate from within the mental health professions through better validation and use of whatever is good in the present system and development of new approaches to replace whatever cannot be firmly validated.

In hope of bridging the gap between the pressing needs of the mental health service system and the scientific principles to which research must adhere, it may be helpful first to consider some possible reasons for the dearth of high-quality research on behalf of disturbed children. Thereafter, I will deal with specific methodological problems that arise in research on child psychopathology. I will conclude with what I consider to be some of the most important needs for research in this area.

Reducing Some Obstacles to Research on Child Psychopathology

The stepchild status of research on child psychopathology results, I think, from the fact that most clinical training is oriented primarily toward treatment of adults. Those who wish to work with children must typically defer child clinical experience until after they have a heavy dose of adult training. Even though adult training may aid in dealing with the parents of disturbed children, it fosters treatment models and attitudes that are inappropriate not only for treating children but also for developing researchable hypotheses about psychopathology in children. The em-

phasis on treatment of adults stems no doubt from the fact that adults have long been the primary paying customers for mental health services. An additional factor may be that treatment of adults offers a glamorous and prestigious role more in keeping with the professional status and personal insights sought by those who enter clinical training. As a result, there has been insufficient incentive to develop an independent tradition of child clinical training and research. Instead, most research on child behavior has been left to academic developmental psychologists who are not attuned to the functioning and needs of the mental health service system. Widening the gulf still further between the "two cultures" of researchers and practitioners is the current preoccupation of clinical psychologists with winning recognition as independent service providers.

Several changes of orientation might help to overcome these obstacles to research on child psychopathology. An especially desirable change would be to make child clinical training a primary specialty rather than allowing it to remain secondary to adult training. This could be done in a number of ways. One way would be to make child training a separate and distinct track coequal with adult training in the larger clinical programs. A second way would be to give more emphasis to the differences between approaches appropriate to children and adults in general clinical training programs, supplemented with instruction in normal child development. A third way would be to encourage more training programs to make child clinical their primary and official emphasis, rather than continuing to have so many child practitioners trained in general clinical programs geared almost exclusively to treatment of adults.

Another desirable change would be in career roles for psychologists whose talents lie in research. A major portion of biomedical research is carried out by full-time researchers who function as members of teams or laboratories specializing in specific organic diseases and abnormalities. By contrast, the dominant model for researchers in psychopathology has been that of the teacher cum researcher cum clinician. Attempts to simultaneously fill all three roles may have interfered with pro-

grammatic research in the best of times, but shrinking resources, the disappearance of teaching positions, and increasing demands on those who do teach mean that alternatives to the primarily academic and primarily service career models must be fostered if behavioral research on psychopathology is to progress.

A further desirable change would be to link the study of psychopathology in children more closely to the study of normal development. This would entail delineating the specific ways in which disorders disrupt the typical course of cognitive, emotional, behavioral, and social development and how the outcomes of various disorders affect long-term adaptation. When considered in a developmental context, some disorders that seem ominous may not in fact be debilitating unless they prevent children from receiving socialization experiences necessary for adaptation to their culture. Other disorders that seem less ominous might have severe consequences if they interfere with the cumulative socialization needed for long-term adaptation. A developmental perspective on child psychopathology would emphasize (a) the transactional relationships between children's characteristics as individuals and the social contexts in which they function and (b) the different implications that various combinations of child and environment have at different developmental levels. Although linking childhood characteristics with adult psychopathology should remain an important goal, research on child psychopathology would benefit from greater reliance on knowledge of normal development than on models of adult psychopathology.

Methodological Problems

The emphasis here will be on problems evident in manuscripts submitted to the *Journal of Consulting and Clinical Psychology*, but they are representative of weaknesses in work appearing elsewhere as well. Although some of the problems are quite general, I will discuss them as they arise in the context of research on child psychopathology.

Subject Characteristics

The choice of subjects in too many studies is determined more by convenience than by

the requirements of sound research design. The design of every study should take careful account of such variables as the developmental level, intelligence, sex, race, socioeconomic status (SES), and clinical status of subjects.

Developmental level. Even small differences in developmental level can have large effects on subjects' capabilities, the ways in which they construe situations, the kinds of experiences they have had, and the behavior they elicit from others. Chronological age (CA) is not an adequate index of developmental level if other relevant aspects of development—such as cognitive ability, physical maturation, academic achievement, or level of schooling—deviate from CA norms for the population to which findings are to be generalized. If intellectual ability deviates from these norms, an index of cognitive level should be obtained, such as mental age (MA) or total raw score on an IQ test. It should be remembered that the IQ is not a measure of cognitive level but of the deviation of an individual's cognitive level from that of a normative group of comparable CA. Matching subjects for IQ or partialing IQ out of relationships among other variables thus controls for differences in cognitive level only if the subjects are of exactly the same CA. Since this is rarely the case, MA is more appropriate than IQ for use in equating subjects for cognitive level, although the choice of a measure for cognitive level should be guided by the questions that the research is to answer. For example, the Performance scale of the Wechsler Intelligence Scale for Children or nonverbal Piagetian measures might be necessary for use with language-deficient subjects, whereas the Binet MA might be more satisfactory for other groups.

If groups with IQs outside the average range are studied, behavioral expectations should be based as much on their cognitive levels as on their CA. A frequent error is to compare the behavior of children having normal IQs to that of retarded children of the same CA and then to interpret differences as reflecting defects inherent in mental retardation. Since retarded children—by definition—have lower MAs than normal children of the same CA, attributing differences to retarda-

tion per se is tautological at best. Worse than being tautological, however, it may be patently wrong to attribute behavioral differences to the IQ differences, because developing more slowly than the norm for one's culture has many consequences besides the effects of whatever causes the slow development. These consequences include stigmatic labels, a high rate of failure when CA-appropriate tasks are attempted, ridicule, deprivation of positive adult attention, and atypical educational regimens. All of these factors may affect learning, personality, and motivational variables not directly affected by slow cognitive development per se (cf. Zigler, 1971).

Researchers must also be sensitive to the possible effects of cognitive level and atypical rates of development in children who do not happen to be called retarded. For example, characteristics other than low IQ earn children labels such as *psychotic*, *delinquent*, or *disadvantaged*. However, the cognitive functioning of such children is often below the norm for their CA. When comparisons with normal children reveal inferiorities, they should not be attributed to psychosis, delinquency, or environmental disadvantages unless the effects of cognitive level and the concomitants of slow intellectual development can be ruled out through comparisons with children matched for cognitive level (e.g., retarded children and/or younger normal children).

Demographic variables. Experiential differences related to sex, race, and SES are as likely to affect behavior as are the experiential differences related to cognitive level. Demographic characteristics of child subjects may also affect the behavior of adult experimenters toward the subjects and vice versa, resulting in interactions between the effects of child and experimenter characteristics (Back & Dana, 1977; Marwit & Neumann, 1974; Quereschi, 1968).

Despite the influence of sex, race, and SES differences, some otherwise high-quality studies describe their samples only as "children," with no mention at all of these variables, much less any indication that their effects were tested or controlled for (e.g., Kent & O'Leary, 1976). In other studies, the analyses of demographic variables are confounded

in such a way as to obscure possible interactions among them (e.g., Gesten, 1976). Although limitations on subject pools and the different incidence of particular disorders in various groups often preclude exhaustive testing of the effects of demographic variables, their distributions within subject samples should at least be described in detail, and analyses involving them should be sensitive to possible interactions. When the effects of such variables cannot be tested, investigators should explicitly note that their findings are limited to populations like those represented by their samples.

Sources of subjects. The settings from which children are obtained can exert major influences on behavior. The different experiential histories, motivational structures, and expectations of subjects obtained through public schools, clinics, residential institutions, and courts can produce major differences in behavior despite similarities in developmental level, demographic characteristics, and diagnosis. It has been amply demonstrated, for example, that the deprivation of adult attention experienced by institutionalized children can affect their behavior on experimental tasks (cf. Zigler, 1971). In addition, because children do not always distinguish among occupational roles within a setting, their attitudes toward familiar adults are likely to generalize to research personnel. It is therefore essential that sources of subjects be clearly described and that the setting be treated as an important variable that can affect results.

Although control over subject and setting variables is usually sought through standardization of instructions and procedures, the variety of settings in which disturbed children typically must be studied may preclude standardization of all relevant variables. Furthermore, the fragmentation of services for children can create selective biases in samples obtained from each setting. Because subject, setting, and sampling variables can seldom be fully controlled, an alternative is to replicate findings with subjects obtained from a variety of settings. Findings that are robust despite differences in settings have the greatest breadth of application, but it is also important to identify the limitations that specific settings impose on findings.

Diagnostic Classification

Perennial controversies over diagnosis reflect the immaturity of psychopathology as a field of study. Even more than adult psychopathology, child psychopathology lacks a coherent conceptual framework for describing and discriminating among disorders, much less for supporting inferences about the etiology, course, or appropriate treatments for specific disorders. Not only is there no accepted diagnostic system, but there are fundamental disagreements about whether diagnosis is a legitimate enterprise at all (cf. Hobbs, 1975). Critics justly contend that diagnostic labels may stigmatize children without gaining them the benefits of appropriate services. Researchers must be sensitive to the whole child and combat indiscriminate summary labels for individual children. Yet there is no way to accumulate and transmit knowledge without conceptual categories. Findings cannot be generalized unless researchers group and describe subjects according to categories that can be reliably used by others.

In the absence of a generally accepted taxonomy, diagnostic classification schemes must be chosen to fit particular populations and research aims. The portrayal of childhood disorders in the official system for clinical records, embodied in the second edition of the American Psychiatric Association's (1968) *Diagnostic and Statistical Manual of Mental Disorders* (DSM II), represents an advance over the first edition of the DSM (American Psychiatric Association, 1952) in being more differentiated and based at least partly on empirical studies. However, no operational definitions are provided for its categories, and the categories do not reflect developmental differences. Furthermore, research indicates that interjudge reliability averages only about 60% for broad categories, such as psychotic versus neurotic, and considerably less for specific subcategories (cf. Achenbach & Edelbrock, in press). The forthcoming DSM III is intended to remedy at least some of these deficiencies, but current drafts inspire no hope of a panacea.

An alternative system has been proposed by the Group for the Advancement of Psychiatry (1966). It is designed specifically for

childhood disorders, is far more differentiated than the DSM II, and reflects developmental considerations. However, like the DSM, its categories consist of narrative mixtures of description and inference formulated by committees of psychiatrists rather than being operationally defined on the basis of empirical research. Interjudge reliability is no better than for the adult categories of the DSM (Freeman, 1971).

A third alternative is to use categories derived through multivariate analyses of behavior checklists. Despite differences in checklists, subject populations, types of raters, and methods of analysis, there is considerable convergence in the behavioral syndromes identified in various studies (cf. Achenbach & Edelbrock, in press). Much remains to be done by way of translating these syndromes into categories of individuals or disorders, but several of the checklists have been sufficiently validated to provide a basis for describing and categorizing disturbed children for research purposes. Even if investigators prefer a different approach to diagnostic classification, the generalizability of their work will be greatly enhanced by scoring subjects on at least one well-validated checklist.

In addition to identifying behavioral characteristics as objectively as possible, it is important to identify any organic conditions and medications that may be relevant. Even in studies focused on nonorganic characteristics, differences in the distribution of organic conditions among subject groups can affect findings. This is just as true for disorders in which organic etiologies have not been proven as for disorders in which organic etiologies are known. As inconclusive as organic diagnoses may be for a particular study, they almost always have potential implications for the findings. For example, in a comparison of black children and white children, it was found that low-IQ black subjects obtained higher Rorschach perceptual integration scores than did low-IQ white subjects (Gerstein, Brodzinsky, & Reiskind, 1976). This was interpreted as indicating that standard IQ tests may underestimate the cognitive capacities of black children. However, the only diagnostic information given was that "all groups were heterogeneous with respect to diagnostic cate-

gory" (Gerstein et al., p. 761). A low-IQ clinic population is likely to contain children with neurological dysfunctions, and, as Gerstein et al. noted, such dysfunctions have been found to be related to poor integrative performance on the Rorschach. It is therefore possible that differences in the distribution of neurological dysfunctions in the black samples and white samples could account for the racial differences in disparities observed between IQ and Rorschach performance. The value of the study could have been greatly enhanced if organic dysfunctions in the samples had been controlled for, their effects tested, or at least reported.

Measures of Children's Behavior

A great many measures of children's behavior have been devised, but few have been adequately standardized and validated for studying psychopathology. Because of the time, sample sizes, and effort required for standardization, investigators are often forced to choose between devising a new measure without adequate standardization or employing a measure that was standardized for populations or uses not entirely appropriate for the investigator's purposes. The result is both a proliferation of measures having unknown properties and an accumulation of apparent failures of standardized measures to deliver what they promised. The latter problem may be due in part to the failure of authors of standardized measures to emphasize the limitations on the populations and situations for which their measures are appropriate. However, because authors cannot foresee all possible uses and abuses of their measures, the measures should not be blamed if they fail to fulfill purposes for which they were not validated. Careful attempts to broaden the application of a measure are warranted as long as poor results are not interpreted to mean that the measure is invalid for its intended purpose. But, lacking an armamentarium of well-validated research instruments, we have a collective responsibility to insure that existing instruments are properly used rather than unfairly undermined through inappropriate applications.

Whether measures have previously been

standardized or are constructed for a particular study, it is always necessary to pilot test them with subjects and conditions like those to be studied in the research. The variability in children's expectations about research situations, their attentional and cognitive limitations, and other variables that affect their responses to research procedures make it essential to obtain a child's eye view of the research situation in order to eliminate sources of anxiety, misunderstanding, response sets, and demand characteristics (cf. Achenbach, 1978b, chap. 7). Careful observation and interviewing of pilot subjects are therefore necessary precursors of all research with children. Once procedures have been finalized, they should be documented and reported in sufficient detail to enable others to replicate them with no inadvertent variations that might affect findings.

Situational specificity of behavior. Whatever position one takes in the debate over the relative dominance of person or situation variance in behavior (cf. Mischel, 1977), it is obvious that children's behavior varies tremendously with the situation. In ratings of normal nursery school children, for example, Rose, Blank, and Spalter (1975) found very little consistency from one situation to another even within a nursery school environment, despite high reliability among observers. This does not necessarily mean that no stable subject variance was detectable, as significant correlations were found between reratings of children in the same *situations* within the nursery school 4 months apart.

In addition to situational effects, the type of observer and his/her relationship to child subjects inevitably affect the behavior reported. The greater the disparity between the situations in which observers view children and the more the observers differ in their relationships to the children, the lower the agreement in observations (cf. Achenbach & Edelbrock, in press). Because there is typically no single criterion situation against which to validate observations, it is important to obtain multiple measures from observers who differ in their relationships with the subjects. Despite their potential biases, parents are usually the key informants regarding behavior of clinical concern, because their per-

ceptions determine what will be done about their children. Furthermore, parents' reports of behavior problems have been found to be much more complete than those of teachers, school observers, home observers, or clinic intake workers (Novick, Rosenfeld, Bloch, & Dawson, 1966). Interparent agreement and the agreement of teachers and clinicians with parents have also been found to exceed agreement between clinicians, as well as agreement between clinicians and teachers (Miller, 1964). Furthermore, clinical trainees' judgments of children's pathology have been found to be influenced more by parents' reports than by direct observations of children in a clinical setting (McCoy, 1976). Whenever possible, studies of child psychopathology should therefore take parent reports into account.

In addition to parents, alternative sources include other family members, teachers, clinicians, peers, and self-reports. The weight given to reports from these sources should depend on the cross-validated accuracy with which they are found to relate to the variables of interest. For example, peer reports may be among the best predictors of behavior in group social situations, teacher reports may be the best predictors of academic functioning, and clinician reports may be the best predictors of behavior during psychotherapy sessions. When reports from various sources disagree, choices must be made about the relative importance of situations to which findings are to be applied.

Developmental versus trait variance. An important goal of most behavioral research is to identify relationships among various measures of behavior. This goal has traditionally been most prominent in trait-oriented research, but it is implicit in any research that seeks to identify enduring individual differences among people, whether or not these differences are viewed as traits. An often overlooked complication of the search for individual differences in children is that developmental differences account for significant variance in almost every measurable behavior. One consequence is that measurements repeated on the same subjects more than a few weeks apart are likely to differ as a function of development, even if the subjects show

stability with respect to their rank ordering within their cohort. A second consequence is that unless all subjects in a sample are at the same developmental level with respect to the behavior in question, individual differences in the behavior may in fact reflect differences in developmental level rather than traitlike characteristics. A third consequence is that covariation among several measures may merely reflect the variance that they all share with development rather than an independent trait.

As an example, impulsivity-reflectivity has been regarded as a dimension of cognitive style that correlates with a variety of behavior in normal and clinical samples. However, it is also known to correlate with CA and MA, indicating that at least some of the variance in measures of impulsivity-reflectivity is shared with indices of development. To determine whether impulsivity-reflectivity represents significant trait variance over and above the variance it shares with cognitive development, Achenbach and Weisz (1975) administered the Stanford-Binet and a test of impulsivity-reflectivity to preschoolers on two occasions 6 months apart. It was found that impulsivity-reflectivity correlated significantly higher with MA than with IQ on each occasion and across occasions. This indicated that cognitive developmental level as measured by MA, rather than deviation from normative age groups as measured by IQ, was the appropriate cognitive measure against which to assess variance in impulsivity-reflectivity.

Although there was a significant correlation between pretest and posttest impulsivity-reflectivity scores, regression of posttest scores on both MA and pretest scores showed that considerably more of the variance in posttest scores could be accounted for by MA than by pretest impulsivity-reflectivity. Furthermore, a significant correlation between impulsivity-reflectivity and hypothesis usage—a behavior assumed central to cognitive style (Kagan & Kogan, 1970)—disappeared when MA was partialled out. It thus appears that general cognitive development may account for much of the variance in impulsivity-reflectivity that has been ascribed to an independent trait. A similar lack of independence from general cog-

nitive development has been reported for field independence (Weisz, O'Neill, & O'Neill, 1975) and for measures of moral development (Taylor & Achenbach, 1975). Before drawing conclusions about variables that correlate with development, it is therefore necessary to demonstrate that they represent reliable variance over and above the variance that they share with general development. Otherwise, we risk a proliferation of "traits" that can be more parsimoniously measured and conceptualized in terms of general indices of development, such as MA and CA.

Avoiding Pathological Biases

It is widely recognized that when people are asked to recall the developmental histories of adults whom the informants know to be disturbed, the reports are likely to be biased in the direction of excessive pathology. Pathological biases of this sort are not restricted to retrospective reports by untrained informants, however. Lacking objective criteria for discriminating normality from pathology, mental health workers may be overly sensitive to signs of pathology. This is especially true where children are concerned, because they may become anxious, constricted, impulsive, or withdrawn when brought to mental health settings, which they view as mysterious, threatening, or punitive. Clinical settings are thus likely to highlight signs of pathology, and the effect of pathological biases on clinical judgments of even the most normal children has been well documented (McCoy, 1976). Research on disturbed children should therefore be grounded firmly on comparisons with normal children matched to clinical samples for conditions of observation as well as for such variables as developmental level, SES, race, and sex.

Correlation, Causation, and Prediction

Causal relationships can rarely be inferred from covariation between variables, unless controlled experimental manipulation of the hypothesized independent variable is followed by corresponding changes in the dependent variable. Experimental designs offer the most powerful means for testing causality, and they

are certainly the most appropriate way to test the effects of variables subject to experimental manipulation, such as treatment conditions. However, true experimental designs are rarely feasible in research on the etiology and developmental course of psychopathology in humans. As a result, much research on psychopathology is correlational. Despite the maxim that "correlation does not imply causation," it is surprising how often statistical covariation is concluded to demonstrate causation without the benefit of experimental manipulation or convergent findings that rule out alternative explanations for the covariation. For example, correlations between child behavior and parent socialization practices have often been interpreted as demonstrating the effects of the socialization practices on children. Yet, as Bell and Harper (1977) have shown, most of these correlations are ambiguous with respect to causation, because they could just as plausibly reflect the effects of children on their parents' behavior, genetic similarities between parents and children, or correlations between the extrafamilial influences that operate on children and on their parents.

Another pitfall of correlational research on children is the tendency to overinterpret correlations in terms of prediction. One source of this tendency is the statistical terminology of multiple regression and discriminant analysis in which the independent variables are referred to as "predictors" of the dependent variable. The summaries of covariation among variables provided by these statistical methods should not be confused with the prediction of behavior across time, however. Unless "predictor" variables are in fact measured earlier than the "outcome" variable and independently of it, they are not predictors in the temporal sense.

A second source of the tendency to overinterpret correlations in terms of prediction is the traditional longitudinal research strategy. A goal shared by research on development and psychopathology is to identify relationships between variables measured at different points in people's lives, and longitudinal studies are the most obvious way to do this. However, significant longitudinal correlations in a particular sample do not necessarily mean

that the earlier variables are predictors of the later variables. Before longitudinal findings are interpreted, it is necessary to determine whether the number of statistically significant relationships substantially exceeds that expected by chance. This is an important step in any research, but longitudinal research offers such inordinate temptations for post hoc analysis that extra care must be taken to control for chance.

Besides controlling for the effects of chance on the distribution of statistically significant relationships, it is important to consider the limitations on generalization of longitudinal findings. Initial selection factors and attrition inevitably undermine the representativeness of longitudinal samples. Moreover, as will be discussed in detail later, peculiarities of particular cohorts and the periods in which they are studied can affect the relationships obtained. Unless they are specifically predicted by a priori hypotheses, covariations between earlier and later measurements in a particular sample are best used to generate hypotheses subject to further test. In rare cases, further tests of the hypotheses may be made with other data from the same samples, or path analysis may be used to choose among competing interpretations (cf. Achenbach, 1978b, chap. 6; Kerlinger & Pedhazur, 1973). More typically, new samples or designs will be needed to replicate and triangulate the relationships obtained in the initial samples. Without replication and further test, significant covariation between earlier and later measurements in a single sample is not a sufficient basis for inferring "prediction," much less causation.

Problems in Measuring Change

At first glance, the measurement of stability and change in behavior appears to be a simple task. However, it is fraught with perils for which there are few simple solutions. I will first consider regression effects and then the problems encountered in using change scores.

Regression effects. Any score can be regarded as a sum of a true score for the variable in question and the errors of measurement that cause the obtained score to deviate

from the true score. Sources of error include momentary fluctuations in the phenomenon being measured, as well as biases and inconsistencies in the measuring procedure. Like most multidetermined phenomena, errors of measurement are assumed to be normally distributed around each of the true scores that would be obtained if there were no errors of measurement. If errors are normally distributed around a true score, extremely large errors will be much rarer than small errors. Therefore, if a large error is made on one occasion, the most probable outcome of a subsequent measurement is a score that is closer to the true score than the first score was. If the first score was extremely high, then the subsequent score will be lower. On the other hand, if the first score was extremely low, the subsequent score will be higher.

To illustrate the way in which regression effects can complicate research, suppose that 100 subjects all have a true score of 50 on variable X. Due to errors of measurement, the actual scores obtained by these subjects on a particular occasion may be normally distributed from 40 to 60, with a mean of 50. Suppose that the same 100 subjects are measured again 6 months later, that their true scores have all remained at 50, and that their obtained scores are again normally distributed from 40 to 60, with a mean of 50. Unless the error of measurement is perfectly reliable from the first to the second occasion, a plot of the relations between each subject's first and second scores will show that subjects who scored lowest on the first occasion now score higher. Conversely, subjects who scored highest on the first occasion now score lower.

Next, suppose that we had performed an experiment to compare the effects of a particular treatment on subjects who initially scored between 40 and 45 on variable X with the effects on those who scored between 55 and 60. Or suppose we could not introduce an experimental manipulation but simply wished to compare the developmental course of subjects who had initially scored low and high on variable X. In either case, we would find the Time 2 scores of both groups to be much closer to the overall mean of 50 than they were at Time 1, merely because the classification of subjects was based on measure-

ment errors that were replaced for those particular subjects by less extreme measurement errors at Time 2. If instead of comparing low and high scorers we had studied the effects of a particular treatment on low scorers, we would have found their Time 2 scores to approximate the mean for the entire sample and might erroneously conclude that the treatment was responsible for the increase in their scores.

Errors of measurement are not the only source of regression effects. Behavioral variables are influenced by so many determinants that even true scores are subject to regression effects from one occasion to another. This is because the lowest true scores on variable X are obtained by subjects who have received the most extreme combination of X-depressing influences. By contrast, the highest true scores on variable X are obtained by subjects who have received the most extreme combinations of X-enhancing influences. Because extreme combinations of influences on X are likely to be due at least in part to chance, the true scores of extreme scorers are likely to regress toward the population mean on subsequent occasions if X is a variable whose true value changes. Thus, children who display many behavior problems on one occasion are likely to display fewer problems on a subsequent occasion due to regression effects. Since most behavioral variables are subject to change—especially variables measured during the course of development—regression in true scores must be expected in addition to regression due to errors of measurement.

Change scores. It would seem logical to compute the difference between an initial score and a later score to measure developmental change over time, as well as change in response to experimental manipulations. However, the size of each change score depends not only on the effects of intervening development and manipulations but also on regression effects. Thus, subjects initially obtaining low scores on a variable are likely to have the largest positive change scores, whereas subjects initially obtaining high scores are likely to have the largest negative change scores.

Even though regression effects may differentially affect change scores of individual high

and low scorers, this would not bias a comparison of groups receiving two different treatments, *provided* that the groups receiving the different treatments had the *same* distribution of initial scores. However, if one group initially scored higher than the other, regression effects could enhance the change scores of one group while depressing the change scores of the other group. Even if change scores are not used, other considerations argue against testing the effects of independent variables with groups differing in initial scores on the dependent variable. Yet, because change scores mask both the initial size of scores and regression effects, they complicate the problem still further.

The most general solution to problems of measuring change is to compare groups that are initially well matched on all relevant variables, including their scores on the dependent variable. Random assignment, stratified randomization, and formation of matched blocks within which treatments are randomly assigned provide the most straightforward ways to obtain comparability. When any form of matching is used, however, care must be taken to avoid biased selection from populations whose distributions differ. For example, parents of lower-SES boys tend to report more delinquent behavior problems than parents of upper-SES boys (Achenbach, 1978a). In order to match lower-SES boys to upper-SES boys on delinquent behavior, it would be necessary to select lower-SES boys whose behavior is less delinquent than the average of their population and/or upper-SES boys whose behavior is more delinquent than the average of their population. However, matching of this sort is fallacious, because, besides being unrepresentative of their SES groups, the boys would be likely to show divergence toward the means of their respective populations on subsequent occasions due to regression effects. Detailed treatment of statistical approaches to the analysis of change is beyond the scope of this article, but advice on compromise solutions to measuring change has been provided by Campbell and Stanley (1963), Cronbach and Furby (1970), Harris (1963), McCall and Appelbaum (1973), and Wilson (1975).

Effects of Age, Cohort, and Time of Assessment

In addition to general problems in measuring change, assessment of behavior that can change with age is complicated by the fact that age differences may be confounded with characteristics peculiar to the cohorts studied and with the effects of cultural conditions prevailing at the time of assessment. Confounding of this sort is most evident when longitudinal conclusions are drawn from cross-sectional data. After considering sources of error in this practice, I will outline various research strategies for separating the effects of age, cohort, and time of assessment. (See Achenbach, 1978b, chaps. 4 and 7, for a more detailed presentation.)

Drawing longitudinal inferences from cross-sectional data. Because longitudinal research is so slow and expensive, it is tempting to use cross-sectional data to infer age changes in behavior. It might seem reasonable to assume that if 6-year-olds in a population behave differently from 16-year-olds in the same population, then the 6-year-olds will change until, when they reach 16, they will resemble the current 16-year-olds. Depending on the behavior in question and the ages spanned, this can be a very risky assumption. Differences in the birth order, SES, cultural experience, health, and schooling of the two cohorts can have powerful effects on their developmental course. Differences in all of these variables and many more can occur even when subjects appear to belong to the same population because they live in the same locality and attend the same schools. The recent decline in the birthrate, for example, means that children who are currently 6 years old will have fewer siblings when they are 16 than do current 16-year-olds. Although the effects of cultural trends are difficult to measure directly, the myriad of uncontrolled variables operating on each cohort makes it risky to infer that cross-sectional age differences reflect the same changes in behavior as occur when a single cohort is studied longitudinally.

One of the clearest contradictions between cross-sectional and longitudinal findings has emerged from the study of IQ test performance at various ages. The norms for the

Wechsler Adult Intelligence Scale (WAIS; Wechsler, 1955), for example, were based on cross-sectional samples that showed progressive declines in performance from early to late adulthood. By contrast, longitudinal data on samples of adults retested at intervals of 12 years have shown significant increases in WAIS performance (Kangas & Bradway, 1971). Likewise, a cross-sectional study of the Binet IQs of southern black children showed progressively lower scores from the younger to the older cohorts (Kennedy, Van De Riet, & White, 1963). However, retesting of the same children 5 years later showed that their IQs had remained stable (Kennedy, 1969). In both cases, the declines in IQ implied by the cross-sectional data were due to differences in cohorts other than their ages: In the WAIS samples, the older cohorts had grown up when average educational attainment was less than for the younger cohorts. In the southern black sample, the cohorts were from 5 to 16 years old but included only children who were in elementary school. This means that the youngest cohorts contained children who were bright enough to begin school early, but the older cohorts contained progressively larger proportions of students who had not been promoted beyond elementary school at the customary age.

Jensen's approach. In a widely publicized alternative to the ordinary cross-sectional design, Jensen (1977) has made cross-sectional comparisons between siblings to test the hypothesis of a cumulative deficit in the IQs of southern black children. He has done this by computing the differences between the IQs of black siblings to determine whether older black children consistently have lower IQs than their younger siblings. He then compared these sibling differences in IQ to those of white children in the same schools. Because the younger and older cohorts were from the same families within each racial group, Jensen hoped to control for the possible effects of cohort differences in gene pool, SES, and other factors that might arise at various ages. Consistent with the cumulative deficit hypothesis, Jensen found that younger blacks generally had higher IQs than their older siblings. The sibling differences were less consistent for whites, indicating no general trend

toward cumulative deficit. Jensen concluded from this cross-sectional finding that the IQs of blacks but not whites were declining with age.

Unfortunately, Jensen's alternative leaves so many possible variables uncontrolled that it does not improve much on standard cross-sectional designs. Without passing judgment on the cumulative deficit hypothesis per se, it is instructive to consider weaknesses of the Jensen study that argue against drawing longitudinal conclusions from even this revised version of a cross-sectional design. First, Jensen at one point describes his sample as including "all of the white and black children enrolled in the public schools of a small rural town" (p. 185), but then he says that "the present data . . . include only subjects ranging in age from 6 to 16 years" (p. 187). Since the school system probably enrolled children younger than 6 and older than 16, Jensen's unreported procedure for excluding subjects could have exerted a bias like that apparent in the Kennedy et al. (1963) cross-sectional study. The inclusion of siblings would not entirely eliminate such a bias. There is also no report of alternative schooling opportunities for either whites or blacks that might cause differential attrition from the public schools at different ages. Nor is there any report of how sibling status was ascertained or of how the distribution of half-siblings and stepsiblings might differ between the races. All of these factors could influence the results of cross-sectional sibling comparisons.

The primary comparisons between the races involved analyses by family size such that the mean IQ differences were computed between each child and each of his/her younger siblings in families having 2, 3, 4, and 5 children, respectively. However, very few white families had more than 3 children. In fact, all four comparisons for 5-child families involved only 2-4 white sibling pairs. Besides the obvious statistical fallacies of reporting and testing means with such small samples and with repeated representation of the same families in these samples, the different distribution of family sizes in the black sample and white sample could interact with birth rank in ways that are not controlled by cross-sectional comparison of siblings. For example,

more of the older black children in the sibling comparisons for each family size were likely to be lower in birth rank simply because the black families were larger on the average. Since neither the birth orders nor the ages were reported for children of each race having each family size, these factors cannot be ruled out.

The failure of Jensen's (1977) sibling-based cross-sectional approach to control for so many variables does not by itself argue for specific alternative explanations for the differences between IQs of black children and their younger siblings. However, because Jensen's approach leaves so many variables uncontrolled, the findings do not enable us to choose among a variety of possible explanations. As an example, one possible rival interpretation of Jensen's findings is that recent improvements in living conditions for black families have produced higher IQs in their most recently born children than in their children born before conditions improved. Nothing in Jensen's data can rule out alternative interpretations of this sort, and neither conventional cross-sectional designs nor Jensen's approach are likely to discriminate between age changes and stable differences between age cohorts.

Separating the effects of age, cohort, and time of assessment. Despite the relative advantages of longitudinal over cross-sectional designs for identifying changes with age, longitudinal designs can also produce misleading results if there is selective attrition of subjects or if only one cohort is studied. Research on a single cohort may obscure the fact that what appears to be an age-related change in behavior is either peculiar to that cohort or is manifested by other cohorts at that point in history, regardless of their ages. In a 2-year longitudinal study of adolescents, for example, Nesselroade and Baltes (1974) found that cultural changes from the beginning to the end of the study had more influence on personality than did age changes. The cohorts ranged from 13 to 16 years in initial age and 15 to 18 in final age, but all four cohorts showed declines in superego strength, social-emotional anxiety, and achievement. As a result, the youngest subjects resembled the oldest subjects at the

end of the study rather than resembling the oldest subjects as they *had* been at the beginning of the study. If a single cohort had been studied longitudinally, it might have been erroneously inferred that the changes in personality were a function of age per se, whereas comparison of the cohorts showed that the changes occurred simultaneously in all four cohorts.

Because age, cohort, and cultural-historical effects may be confounded in conventional cross-sectional and longitudinal designs, it is important to separate these variables as explicitly as possible in any studies of development, normal or abnormal (cf. Schaie, 1965). As an aid to separating these variables conceptually, the relevant relationships between them are illustrated in Table 1. Table 1 shows that a cross-sectional study comparing 5-, 7-, and 9-year-olds in 1978 would require children from cohorts born in 1973, 1971, and 1969, respectively. A threat to the internal validity of this purely cross-sectional design is that differences between the 5-, 7-, and 9-year-olds might be attributable to characteristics other than age. A threat to external validity is that any similarities or differences among cohorts might not be generalizable to earlier or later points in time because of cultural-historical changes.

As illustrated in Table 1, a longitudinal study of the 1975 birth cohort at ages 5, 7, and 9 would require assessing the 1975 cohort in 1980, 1982, and 1984. The internal validity of this design is vulnerable to the possibility that differences found from 1980 to 1982 and 1984 might be due to cultural-historical changes rather than to aging per se. The external validity may be limited by peculiarities of the cohort that distinguish it from cohorts born earlier or later.

A third design, the time-lag design, is sometimes used to identify cultural-historical effects. As illustrated in Table 1, historical changes in the behavior of 11-year-olds could be studied by assessing subjects from the 1969, 1971, 1973, and 1975 cohorts when they reach age 11 in 1980, 1982, 1984, and 1986, respectively. However, this design confounds possible differences in the cohorts with differences in year of assessment.

To avoid confounding age, cohort, and time

Table 1
Interrelationships Among Time and Age Variables Involved in Developmental Analyses

Birth cohort	Age

^c Longitudinal.

of assessment, several designs have been developed to combine aspects of the cross-sectional, longitudinal, and time-lag strategies. The Nesselroade and Baltes (1974) study of adolescent personality combined these strategies in a *longitudinal sequential design*. By assessing several birth year cohorts over the same longitudinal period, it is possible to do cross-sectional comparisons of cohorts at any point in the study, longitudinal comparisons of each cohort, and time-lag comparisons among cohorts as they reach a particular age in successive years, as illustrated in Table 2. It can thus be determined whether changes in behavior are attributable to cultural-historical changes, age changes, or an interaction between the two.

Another design—the *cross-sectional sequential design*—combines cross-sectional and longitudinal strategies by making cross-sectional comparisons of samples from several cohorts at several different points in time. As illustrated in Table 2, the pattern of analyses is similar to that in the longitudinal-sequential design, except that instead of longitudinally following one sample from each cohort, new samples are drawn from each cohort at each time of assessment. Drawing new samples avoids biases affecting longitudinal studies due to attrition, the effects of repeated testing of the same subjects, and initial selection for expected availability. On the other hand, because new samples are drawn for each assessment, changes in individuals over time cannot be traced, and congruence among suc-

^a A single sample from each of three cohorts is assessed on three occasions from 1978 to 1980.

^b Three samples are drawn from each of three cohorts on three occasions from 1978 to 1980.

^c Three samples from each of three cohorts are compared on three occasions from 1978 to 1980, 1979 to 1981, and 1980 to 1982, respectively.

cessive samples may be reduced by unrecognized sampling fluctuations and changes in the composition of the cohorts from which the samples are drawn.

In an additional design, known as the *time-lag sequential* design, two or more samples are assessed from each cohort as they reach different ages in different years. As illustrated in Table 2, such a design could be used to study the behavior of the 1971, 1972, and 1973 birth cohorts as they reach the ages of 7, 8, and 9 in 1978–1982, respectively. This design permits separation of effects due to time of assessment from effects due to age of assessment without requiring longitudinal samples. However, like cross-sectional sequential designs, the time-lag sequential design is vulnerable to variations in samples from the same cohort. The chief advantage of this design is to obtain information on the effects of cultural–historical changes with fewer observations than longitudinal sequential or cross-sectional sequential designs would require.

Outstanding Research Needs

There is no doubt that research on child psychopathology is in a rudimentary stage and that it faces many challenges. Perhaps the greatest challenge is to accept the task of forging a science suitable to the problems despite the primitiveness of our knowledge base and the influence of myth, fad, and custom. Other challenges can be summarized in terms of general needs as follows: the need to view children as continually changing with respect to biological, cognitive, social, educational, and emotional development; the need to assess behavior in relation to development that is normal and adaptive within the child's culture; the need to evaluate current behavior from a longitudinal perspective on what has gone before and what is likely to follow; the need to see children's behavior in a family context over which children have little control; the need to develop alternatives to mental health services that require the recipients to assume the role of patient; and the need to abide by ethical constraints without abdicating our responsibilities to seek knowledge that will benefit troubled children. A thorough discussion of the latter issue is beyond the scope of this article, but it is clear that the pendulum swing from inadequate ethical guidelines to minute regulation of everything labeled *research* presents formidable obstacles to the study of child behavior (cf. Achenbach, 1978b, chap. 10). However, lacking validated means for helping troubled children, we must consider not only the ethics of specific research procedures but, to paraphrase Haywood (1977), the ethics of *failing* to do the research needed to improve our ways of helping children. In addition to the general needs facing research on child psychopathology, a number of needs specific to our current stage of development are outlined in the following sections.

Standardized Measures

The handicaps stemming from our lack of well-validated and standardized measures have already been alluded to, but insufficient effort is currently devoted to remedying this situation. Although highly sophisticated in-

umentation requires well-refined and validated theory, it is equally true that theory is unlikely to progress without reliable descriptions of the phenomena in question. The development of standardized descriptive instruments for behavior is a slow, arduous, and unglamorous enterprise that is effectively discouraged by our graduate training programs, reward systems for researchers and teachers, professional journals, and funding agencies. In the face of such obstacles, is it any wonder that our standardized instruments are limited primarily to IQ and achievement tests, which owe their existence to subsidies from the educational system?

If it is acknowledged that research on child psychopathology is indeed in a rudimentary stage, it should be clear that development of standardized procedures for assessing pathologies and competencies and for measuring change in them should command a high priority. The more diverse the sources of data (parents, teachers, peers, clinicians, self-reports) and the greater the focus on important life situations, the more useful such procedures are likely to be. It is only when researchers and clinicians can rely on a common body of baseline measures that we are likely to see significant coordinated advances in knowledge.

Type of Subject \times Type of Treatment Designs

A vast quantity of research has accumulated on the outcome of adult treatment. However, the value of this research has been unduly limited by the heterogeneity of its subject samples, without adequate regard for differences among the subjects. The much smaller quantity of research on child treatment shares the same flaw, despite the fact that when subject characteristics have been analyzed, their effects have been found to account for more variance in outcome than do differences in treatment alone (e.g., Love & Kaswan, 1974; Miller, Barrett, Hampe, & Noble, 1972). Because it should be obvious that no single treatment modality will be better than all other modalities for all children regardless of age, sex, IQ, SES, family constellation, and so forth, we should not have to

repeat the history of adult psychotherapy research before we recognize that outcome studies will be most informative if they take account of subject variables and especially of Subject \times Treatment interactions.

Subject \times Treatment designs are, of course, even more difficult to implement than ordinary controlled studies of treatment outcome, which are themselves formidable. However, because the effects of most interventions are likely to be subtle and multidetermined, it is essential that interventions not be viewed independently of the children with whom they are used. Any outcome study that provides systematic comparison of results for children differing in demographic, diagnostic, and other characteristics will be far more valuable than studies that do not.

Long-term Follow-ups

Although by no means infallible, the most comprehensive approach to determining the significance of potential predisposing factors and manifestations of psychopathology in childhood is through long-term follow-ups. It has become evident that even major adult psychiatric disorders such as schizophrenia may be best understood through longitudinal study of children who are at high risk for the adult disorder (Mednick, Schulsinger, Higgins, & Bell, 1974). Because of the relatively low base rate for severe psychopathology in the general population, long-term study of subjects known to be at risk is more efficient than traditional longitudinal studies of broad samples of children. However, studies of broad samples can also be informative with respect to psychopathology if they are sufficiently focused on the context and course of disorders that a large percentage of children manifest at least temporarily (Thomas, Chess, & Birch, 1968). As mentioned earlier, relationships identified in single cohorts studied longitudinally provide an inadequate basis for definitive inferences, but the complexity of human behavioral development and the rudimentary state of our field make longitudinal data a unique source of hypotheses for further test, even if the effects of age, cohort, and time of assessment cannot be fully separated.

In addition to basic longitudinal research, it is important to build a longitudinal dimension into studies of treatment outcome. Unless adequate follow-up periods are used, it cannot be known how interventions will affect the behavioral, social, emotional, cognitive, and educational development of children. Successful adaptation depends not merely on the removal of troublesome behavior but also on the continued acquisition of progressively more advanced coping strategies. Studies that include follow-ups of even 1 or 2 years often show results quite different from shorter follow-ups of the same children (e.g., Hampe, Noble, Miller, & Barrett, 1973). Arduous though they may be, follow-ups over periods of at least a year should become a routine part of clinical services, as well as of research on these services.

Cumulative Programmatic Research

The volume of publications related to child psychopathology far outweighs its actual impact. Although no field shows a linear progression of knowledge, especially during its formative stages, the literature on child psychopathology reflects two problems that may be remediable. One is the preponderance of one-shot studies whose contribution to knowledge is limited by the uniqueness of their procedures, measures, and subject samples. Since almost no study provides definitive answers by itself, a study is of little value if it cannot be linked to others for purposes of replication, generalization, cross-validation, and triangulation of findings.

The preponderance of one-shot studies is not surprising in view of the obstacles to programmatic research encountered by the graduate students, academicians, and practitioners who have been the chief contributors to our literature. However, unless research can be better coordinated with respect to procedures, measures, and subject samples, and unless each study can be meshed better with what comes before and after it, new studies will add more confusion than knowledge. As stated at the beginning of this article, opportunities are needed for career researchers who can pursue programmatic studies more effectively than people who are also carrying heavy

teaching and/or clinical responsibilities. In addition, graduate students and others who are limited to doing one-shot studies should be encouraged by their advisors and by journal policies to link their work as closely as possible to other research through the use of standardized measures, procedures, and subject samples that can be generalized and replicated. By their sanctions against closely linked series of studies, graduate committees and journal editors may otherwise be perpetuating fragmentation where convergence is needed.

A second impediment to cumulative progress is the tendency for practitioners and researchers alike to identify with a single theoretical viewpoint. This has resulted in what might be called a "horizontal" progression within each school of thought, rather than a "vertical" progression, whereby ideas from various sources are tested and revised or discarded according to the empirical findings they generate. As productive as research within a single paradigm may sometimes be, no single theory or level of analysis is yet so powerful for representing child psychopathology that it deserves exclusive allegiance. In the foreseeable future, cumulative knowledge is more likely to emerge from integration of multiple perspectives than from dogmatic adherence to a single one.

Linking Research to Service Systems

The ultimate aim of research on child psychopathology is to aid children by preventing maladaptive development and by ameliorating it when it does occur. Children receiving treatment through the current mental health system represent only the tip of a very large iceberg that encompasses the educational, legal, medical, and welfare systems. When direct mental health services are available for children at all, they are often sought only after the other systems have failed. These systems are ill equipped to identify and correct maladaptive deviations in behavioral development, but they are representative of the social context in which children develop. It is within this context of mixed motives and messages, competing agendas, maldistribution of resources, and bureaucracy that the fruits of research must ultimately be consumed.

None of the systems is designed to foster research, much less to implement its findings. Even though the mental health system should be the most responsive to research on child psychopathology, it raises barriers of its own. It is clear, for example, that the personal philosophies of mental health practitioners determine the treatments received by clients to a far greater extent than in organic medicine. The concomitantly greater difficulty of changing one's approach to treatment of psychopathology than of trying out a new medication for an organic disorder probably accounts for the resistance of many practitioners to participating in research and to adopting new approaches, no matter what research shows about their customary approach. On the other hand, research related to treatment of children has rarely offered practitioners well-validated alternatives to their customary approaches. Is it therefore surprising that little effective cross-fertilization occurs between research and practice?

To promote cross-fertilization as well as to increase the ecological validity and potential application of their work, researchers must gear their work as closely as possible to the needs of practitioners and must provide practitioners with usable results in a constructive manner. It is only through implementation in practice that researchers can obtain feedback on the effectiveness of their efforts.

Sex Roles and Psychological Well-Being: Perspectives on Methodology

Judith Worell
University of Kentucky

The purpose of this article is to delineate some sources of problematic methodology in recent research designed to relate current measures of sex-role orientation to indices of psychological well-being. Practices and procedures in sex-role research are examined in relation to orthogonal scales of sex-role orientation that provide independent measures of masculinity, femininity, and a newer assessment of androgyny. Directions for increased conceptual and methodological clarity include theoretical and psychometric definitions of androgyny, the relationship of sex-role typing to other aspects of interpersonal functioning, and varying procedures in sex-role and gender distinction, population sampling, and construct validation. Issues are raised concerning the generality of sex-role measures and the desirability of direct behavioral validation criteria.

New formulations of psychological health and well-being have renewed an interest in the measurement of masculinity and femininity (Bem, 1974; Berzins, Welling, & Wetter, 1978; Constantinople, 1973; Heilbrun, 1976; Spence, Helmreich, & Stapp, 1975). In contrast to earlier conceptions of sex-typed personality descriptions that relied on a single bipolar dimension, recent approaches to assessment of masculinity and femininity view these as independent, orthogonal dimensions. When treated in this manner, characteristics of masculinity and femininity can be measured in varying amounts in the same individual. Persons are considered to be sex typed to the extent that they endorse a relatively high degree of one set of characteristics in preference to the other. The most conceptually productive outcome of the orthogonal model of sex typing is androgyny, whereby the person endorses relatively equal numbers of masculine and feminine traits (Bem, 1974). The

flurry of new scales to measure androgyny has been followed by a storm of research designed to relate responses on these scales to "something else."

The aim of this article is to examine the methodological characteristics of recent research on psychological sex roles, with the intent of clarifying some current practices and procedures in relation to commonly accepted criteria of research design and analysis. Since earlier reviews have considered at length and in detail the psychometric properties of both traditional and recent sex-role scales (Constantinople, 1973; Kelly & Worell, 1977; Worell, Note 1), issues in scale construction will be minimized here. The focus of the present remarks will be on the implications of current sex-role personality measurement and research for conceptions of psychological health and personal well-being.

The theoretical link between sex typing and adjustment has been altered dramatically since the introduction of the androgyny model. Traditional formulations of sex typing suggest that adoption of the sex roles appropriate to one's male or female gender is developmentally desirable. Deviations from culturally sanctioned sex-role behavior were considered maladaptive and undesirable (Kagan, 1964; Kohlberg, 1966; Mussen, 1969). In contrast,

Appreciation is extended to Suzanne Martorano, to Mary Jo Moeschl, and to two anonymous reviewers for their many helpful suggestions in the preparation of this manuscript.

Requests for reprints should be sent to Judith Worell, Department of Educational Psychology and Counseling, Dickey Hall, University of Kentucky, Lexington, Kentucky 40506.

the androgyny model of sex-role organization suggests that a relative balance of sex-typed characteristics may lead to the most advantageous outcomes. It is important to examine the recent research strategies in relation to the differing assumptions that underlie the selection and interpretation of dependent variables. Androgyny has been compared to sex typing in relation to one or more of the following outcomes: (a) adaptive, flexible, and effective interpersonal behavior; (b) self-esteem or positive self-evaluation; (c) freedom from obvious pathology; and (d) broad life-style coping variables. Each of these adjustment criteria will be discussed in the context of current sex-role research. Since this discussion is not intended as a review of the literature, only selected illustrative examples will be included.

Bem (1974, 1975, 1976) conceives of the androgynous person as adaptive, flexible, and effective in particular interpersonal contexts. Accordingly, the androgynous person can be both *instrumental* (assertive, competent, forceful, independent) and *expressive* (nurturant, warm, supportive, compassionate), depending on the demands of the situation. The outcome of an androgynous orientation is a high degree of alternative options for attaining interpersonal reinforcement in situations requiring culturally sex-typed behaviors. On the Bem Sex-Role Inventory (BSRI), androgyny was originally scored as the relative balance, determined by a negligible *t* ratio, between masculine and feminine sex-typed characteristics (Bem, 1974). In contrast, sex-typed persons scored significantly higher on either their masculine or feminine sex-role traits. Bem considers the sex-typed individual to be more constricted and behaviorally limited in situations in which sex-inappropriate, or cross-sex-typed, behavior is required. Individuals who are highly masculine or feminine sex typed may inhibit or suppress these cross-sex behaviors to avoid self- or other-disapproval.

In a series of construct validation studies using the BSRI, Bem and her associates provided some support for these predictions. Sex-typed individuals did show discomfort and self-defeating choices (monetary loss) in cross-sex situations. In addition, the sex-typed

males showed lowered supportive, playful, and expressive behaviors across several situations, and sex-typed females failed to maintain independence under external pressure to conform (Bem, 1975; Bem & Lenney, 1976; Bem, Martyna, & Watson, 1976). These apparent deficits in the behavioral repertoire of sex-typed, in comparison to androgynous, persons lend support to a flexible-restrictive interpretation. If psychological health and well-being are defined in terms of the availability of behaviors for achieving interpersonal satisfaction, then according to Bem, there may be many instances in which sex-typed persons are clearly at a disadvantage.

A second important dimension of psychological well-being entered into the issues surrounding the measurement of androgyny. Using the Personal Attributes Questionnaire (PAQ) of sex-role endorsement, Spence et al. (1975) found that both male-valued and female-valued scores contributed to a measure of self-esteem. These authors suggested that masculinity and femininity may contribute in an additive way to an individual's positive self-evaluation. Consequently, their definition of androgyny included absolute strength as well as the relative balance of masculinity and femininity scores. The decision to include absolute strengths of each sex-role dimension resulted in a fourfold index, determined by a median split of the combined male and female PAQ scores. Here, the androgynous persons are those who score above the median on both masculinity and femininity. A new category, consisting of those who score below the median on both scales, is termed *undifferentiated*.

The utility of the fourfold scoring system for conceptions of positive well-being was demonstrated in the correlations between the PAQ and a measure of self-esteem. When androgyny was defined in terms of both response strength and balance, androgynous persons were the highest in self-esteem, followed by those who scored high masculine-low feminine, or sex-typed masculine. When Spence et al. rescored these data according to the Bem balance method, androgynous persons scored at only a moderate level of self-esteem. The implications of these findings for positive psychological functioning have led to the adop-

tion of a four-quadrant scoring system by Bem (1976, 1977), as well as by developers of two more recent sex-role inventories (Berkins et al., 1978; Heilbrun, 1976). The scoring issue is not a closed one; some researchers continue to use and defend a balance, rather than an absolute strength, definition of androgyny (Jones, Chernovetz, & Hansson, 1978; Wiggins & Holzmüller, 1978). As currently conceptualized, however, most researchers have preferred to include the absolute strength of masculine and feminine characteristics as an indicator of positive and effective interpersonal functioning. From a response repertoire approach to adaptive situational behavior, the person who endorses more positive self-characteristics appears to have higher self-esteem and should be functional interpersonally in a wide variety of culturally sex-typed situations.

A third indication of effective psychological functioning is the extent to which individuals can remain relatively free from obvious pathology or self-defeating patterns of behavior. Sex-role measures have been variously related to such adjustment indices as anxiety, self-criticism, dependency, helplessness, depression, problem drinking, neurosis, introversion, and requests for personal counseling (Baggio & Neilson, 1976; Deutsch & Gilbert, 1976; Gump, 1972; Heilbrun, 1968; Jones et al., 1978). Since androgynous persons are assumed to be more adaptive, they should have better coping skills and be relatively free of problem behaviors. One concern related to this aspect of adequate psychological functioning is the extent to which individuals provide themselves with negative self-communications and negative self-evaluations (Bandura, 1969; Mahoney, 1974; Meichenbaum, 1977). Although at least two of the presently used sex-role scales (BSRI; PAQ) confine their attributes to positive and valued characteristics, the contribution of negative self-attribution to sex-role categorization has implications for all of the adjustment indices listed above (Kelly & Worell, 1977).

Recent evidence suggests that androgynous males, and some androgynous females, endorse the fewest negative self-statements (Kelly, Caudill, Hathorn, & O'Brien, 1977; Wiggins & Holzmüller, 1978). In contrast to these

positive findings, androgynous males were also found to contribute more than their expected proportion to self-reported problem drinking and social introversion (Jones et al., 1978; Wiggins & Holzmüller, 1978). The research findings in this area of adjustment pathology remain cloudy and inconsistent, especially with regard to androgynous males. Sex-role functioning, as defined by the present measures, may have differential prediction for some psychopathological variables, but no consistent pattern has emerged.

Finally, some investigators have hypothesized that the flexibility presumed to operate in instrumental and expressive domains will be manifested in more effective functioning in a wide variety of cognitive and interpersonal life-style variables. Research efforts in this direction have attempted to relate sex-role types to such variables as creativity, liberal political views, endorsement of feminist views, sexism, marital adjustment, parenting skills, multiple personality factors, and preferred coital position. In some of these studies, the theoretical relationship between effective psychological functioning and androgyny seems quite tenuous. The general theme seems to be that androgynous persons ought to be better at everything, because they are presumably more flexible and adaptive. When androgyny is approached from this viewpoint, it frequently slips into becoming a contest between white hats and black hats.

The discussion of the theoretical underpinnings of current androgyny research becomes important when we take a look at some of the methodological problems that beset the research efforts in this field. In the remainder of this article, I wish to consider the more glaring examples of questionable practices, as well as some of the better ones, in the conceptualization, design, and analysis of research into the nature of psychological sex roles. In doing so, examples will be drawn as prototypes from both published and unpublished research and will be unreferenced. The purpose here will be to organize and discuss these problems in the spirit of constructivism, rather than to point a finger at any particular culprits. The intent of this discussion is to inject a dose of preventative thought and reflection at the early planning stages so that

small problems in design and presentation can be remediated or obviated.

Problems and Practices

The following discussion will generally approximate a theory, design, procedure, and analysis format. Specific topics to be covered are (a) application of theory to design; (b) sex-role and gender distinctions; (c) sampling practices; (d) test and construct validation procedures; and (e) psychometric and statistical considerations. A final section will deal with some unresolved issues.

Theory and Rationale

A substantial portion of manuscripts on sex-role issues fail to explicate a theoretical foundation for the research. This is especially true when a variety of tests or measures are administered. Frequently, little consideration is given to the constructs being measured and their proposed relationship to any sex-role theory. In particular default are studies that take a "one-shot" or a "statistical dragnet" approach. In the one-shot approach, the researcher tends to oversimplify the task of construct validation, implying that any one instance or situation can possibly confirm or negate a psychological concept. For example, suppose a researcher finds that sex-role categories do not predict which women wish to be addressed as Ms., rather than Miss or Mrs. Does this finding negate the utility of the androgyny construct? In a similar mode, the statistical dragnet technique correlates a variety of tests and measures with scores on a sex-role scale. The empirical analysis then capitalizes on a handful of unpredicted results that may disappear in cross-validation. Such atheoretical approaches tend to be devoid of sustained consideration for the particular sex-role-relevant characteristics they are measuring and what they expect to find. The result is frequently a *mélange* of miscellaneous studies and unrelated information that contribute little to progress in current sex-role research.

Although it is reasonable to admit our ignorance in the early stages of exploring androgyny, surely there are some organizing

hypotheses that prompted the research in the first place. Even a replication study might discuss briefly (a) why this study is useful for the procedures it intends to replicate, (b) what it expects to accomplish with this particular sample, and (c) what the implications and/or limitations are in advance of what the results might uncover. What has occurred in the area of sex-role research is a rash of new scales and a bevy of eager researchers who wish to relate androgyny to everything and anything.

There also appear to be a number of confusions and disagreements concerning the theory behind the androgyny research. Bem, for example, limited her conceptions of flexibility to situations that require effective, interpersonal, and culturally sex-typed behavior. Suppose a researcher wishes to extend this notion of flexibility to preferences for differing coital positions. Here, it is important to specify in advance the evidence for any particular position to be sex-role appropriate or inappropriate. Only in this manner can we conclude that sex-typed persons tend to inhibit cross-sex behavior or that androgynous persons can comfortably engage in particular practices. Likewise, if one wishes to correlate sex-role types with acceptance of the women's liberation movement, what is the basis for predicting a favorable response from androgynous individuals? If a man describes himself as warm and supportive, does this necessarily mean that he is willing to assume responsibility for dirty dishes and diapers? Perhaps this is a viable prediction, but again, it requires considerable support in advance. This issue also touches on the distinction between sex-role traits and sex-role behaviors. Within the present context there is no *a priori* reason why sex-role traits cannot be predictive of a broader band of sex-role behaviors than those encompassed by the instrumental and expressive domains. In practice, however, the basis of this type of extended prediction is frequently unclear, making the results uninterpretable.

Cross-cultural and contrast-group studies can be particularly fertile for application of androgyny theory to sex-role research. Since the scales currently in use were constructed and standardized on middle-class American

college students, hypotheses can be tested on how subcultures and differing vocational or interest groups compare. In these contexts, it is the responsibility of the researcher to propose some hypotheses about pertinent differences in cultural norms or sex-role practices and how these might effect the obtained results. Sex-role stereotypes in Formosa or Brazil may indeed differ from U.S. responses, but how do the obtained data articulate with the cultural standards or role demands of each culture? Similarly, there are implicit population hypotheses embedded in an assessment of sex-role responses of homosexual persons that may or may not be logically derived from a sex-role theory. Findings that indicate no differences in sex-role endorsement between specified groups and published college norms may have important implications for the theory or they may be allocated to the "so what" catch-all box.

The inappropriate application of theory to a particular measurement instrument, to a class of behaviors or traits not directly related to the theory, or to miscellaneous contrast populations may result in a premature rejection of hypotheses derived from the theory. If an investigator uses a sex-role measure to predict to a wider band of behaviors than those encompassed by the theory, or to a tangential class of responses, negative findings do not negate the theory. For example, an investigator wishes to test the hypothesis that androgynous persons are more adaptive than sex-typed individuals. A sex-role scale and an anxiety scale are administered; androgynous males turn out to have higher anxiety scores than sex-typed males. Does this finding imply that androgynous males are less, rather than more, adaptive? And does this finding point to a hole in the theory? When using a particular scale, or dependent measure, to assess predictions from a specific androgyny scale, it is extremely important to differentiate the scales (e.g., PAQ, BSRI), the construct (androgyny), and the theory (adaptability). In this case, the negative findings do not necessarily imply a useless theory, a questionable construct, or an invalid sex-role scale. A competing hypothesis might suggest that the higher anxiety of androgynous males reflects their awareness of their unorthodox match

with culturally prescribed standards for masculine behavior. The high obtained anxiety scores for androgynous males may expand our information about this sex-role group, but it does not invalidate previous findings that androgynous males are more willing than sex-typed males to engage in cross-sex behaviors.

How can these problems in relating theory to design be avoided? In the planning and conceptualization stage of sex-role research, the investigator might consider the following: (a) Relate the present research topic to previous findings; (b) state clear experimental hypotheses; (c) relate these hypotheses to some aspect of sex-role theory; (d) state expected outcomes for each hypothesis; and (e) indicate the conditions and limitations under which the hypotheses might support or fail to support the theory. Although these five steps may not eradicate all of the problems in application of theory to design, they may help to prevent unproductive forays and dead-end journeys.

Sex-Role and Gender Distinctions

Judging from the types of designs and statistical analyses that appear in current manuscripts, disagreements exist on how to deal separately with the effects of sex role and gender. Here, gender refers to categorical distinctions between males and females regardless of their behaviors. Sex roles and sex typing will be applied to cultural expectations about the attitudes, beliefs, and behaviors associated with masculinity and femininity. Constantinople's (1973) landmark review presented clear arguments for rejecting gender differences in response as a criterion for item selection or scoring procedures for masculinity-femininity scales. The *raison d'être* of the four sex-role scales referenced here was the measurement of sociocultural sex roles or traits independent of their distribution by gender.¹ Although gender and sociocultural

¹ Two of the four scales under discussion, the PAQ and Heilbrun's Adjective Check List (ACL), have components of gender differentiation built into the structure of the scale. The PAQ contains a separate Masculinity-Femininity scale on which items have been selected by gender discrimination. The

sex roles are not completely independent of each other, they are by no means isomorphic. This distinction has been violated or ignored in at least three major ways.

First, we would like to know whether the functional properties of sex-typed roles or traits are similar for males and females. Some studies have divided subjects by sex type alone, ignoring the Sex Type \times Gender interactions that have appeared in the literature. Some of the obtained interactions between sex types and gender may have distinctive adjustive implications for males and females. Likewise, cross-sex typing appears to function in different ways for the two genders in some studies. The early findings on the functional relationships between gender and sex roles are fragmentary and scattered. Many studies fail to isolate enough cross-sex-typed persons to analyze, but the specific results are suggestive. Further research should clearly include both gender and sex-role considerations.

A problem related to that of the Sex Role \times Gender interaction is the failure to specify the gender distribution of subjects who make judgments or attributions of sex-typed behavior (32 counselors in training were asked to judge . . .). In a similar vein is the failure to analyze for gender even when it is specified and available as an independent variable (36 counselors, 14 males and 22 females, were asked to rate . . .). Surely we are throwing away much valuable data that should be examined rather than swept under the rug. In either instance, the resulting data will not be very meaningful.

The second violation of the Sex Type \times Gender dichotomy is the treatment of data according to gender rather than sex role in assessing or determining sex roles and traits. The effects of sex role and gender should be carefully separated so that we can determine the contributions of each variable. Consider the following examples: To demonstrate that two tasks are sex-role appropriate, the investigator shows that these tasks discriminate the choices of males from those of females. A second example reflects a similar Gender \times Sex

Role contamination. Males and females are assigned to sex-role groups on the basis of a median-split procedure computed with separate male and female frequency distributions. Similarly, sex-role groups are compared on a dependent measure, such as the Minnesota Multiphasic Personality Inventory or introversion-extraversion, the *T* scores for which were computed using separate male and female distributions. In each of these examples, the implications for the resulting data and interpretations may differ. Especially in the latter case, this practice may alter the value of some of the criterion measures and may distort the data in the direction of artificial gender differences. These practices may mask sex-role differences, or Sex Role \times Gender interactions, or they may have no significant effects at all. In each case, the problem can be resolved by examining the data in both ways. Having agreed that sociocultural sex roles and gender are not isomorphic, let us not throw them both into the same pool so that their separate effects become diluted and indistinguishable.

A third confusion concerns the stated purpose of current sex-role scales. The purpose of these instruments is to measure sociocultural sex roles or traits orthogonally and independently of gender. The criterion of relative independence has been the demonstration of a low correlation between the masculinity and femininity scales on each measure. With some exceptions, each scale meets this criterion. Now, an investigator repeats the correlation procedure, supports the scale independence, and concludes that the test is invalid because it fails to discriminate males from females. Or similarly, finding that masculinity and femininity scales on a measure of androgyny do differentiate males from females to some extent, the conclusion is again reached that the sex-role scales are bipolar rather than two-dimensional and orthogonal. In each instance, the purpose of the scales is misunderstood.

Gender and sex-type confusions can be avoided primarily by reversing the procedures above that produced the original contamination. (a) When using sex role as an independent variable, include gender as another variable and analyze for each variable separately.

ACL items were originally selected by differentiation between males who identified with masculine fathers and females who identified with feminine mothers.

In addition, look for possible interactions (providing that the design is appropriate for interactions to appear). (b) Compute median splits for assigning sex-role groups by combining male and female data into a single distribution. (c) Use raw scores on dependent variables in place of *T* scores to avoid criterion problems. (d) Read relevant references, such as Constantinople (1973), Bem (1974, 1977), and Spence et al. (1975), before embarking on any new sex-role research. (e) A writing style addition to this topic is in order. Use a consistent notation to refer to gender (male, female) or to sex roles (masculinity, femininity, androgyny). Frequent changes within an article in notation can leave the reader confused.

Sampling Procedures

Adequate sampling procedures are critical to all areas of psychological research. Certain sampling problems appear particularly relevant to sex-role research because the socio-cultural definitions of sex types and sex-appropriate behavior may vary across populations, generations, and settings. College sophomores participating in experiments for course credit present the fewest sampling challenges; they are available in both genders, in sufficient numbers, and are relatively homogeneous on many relevant characteristics. Restricting all of sex-role research to college students, unfortunately, leaves us with many unanswered questions about the generality of results and the applicability to contrast populations. Those researchers who brave the real world to measure other kinds of people face many more hazards in meeting the requirements for an adequate sample. Therefore, it is particularly incumbent on researchers who leave the college classroom to make certain that their samples meet at least four requirements: Make sure that (a) sample characteristics and selection procedures are recorded and clearly described, (b) samples are sufficiently large and (c) representative to allow generalization to new groups, and (d) the criteria for selection of contrast populations are clearly defined. In the absence of any one of these requirements, the experimental findings may be difficult or impossible to inter-

pret, and the results may have little applicability to other populations. Examples of each of these may clarify the position.

Insufficient descriptions of sampling procedures and population characteristics guarantee that a research design cannot be appropriately replicated. To relate a set of findings to a larger body of sex-role research, it is important for the reader to be informed of the exact *N*, age or age range, gender, and whatever other demographic characteristics of the participants are deemed relevant. For sex-role research, information on career, marital, and educational status might be important. Readers also wish to know how the subjects were enlisted and what the conditions were under which some subjects dropped out or were eliminated from the sample (mortality). Some recent examples of inadequate descriptions include such statements as "20 housewives returning to school were administered . . ." or "30 graduate students at University X in Calcutta were approached and asked. . . ." These vague sample descriptions do not help us to accumulate a body of useful data from which to generalize either to similar or to contrast populations. In cross-cultural research, in which the impact of national characteristics is examined, the appropriate match between cross-national samples becomes critical.

A similar caution is appropriate when examining sex typing in clinical groups such as male alcoholics or female depressives. Unless the demographic characteristics of the clinical population are carefully described and matched with an appropriate control group, sex-role differences may be ascribed to the dynamics of the clinical syndrome that are probably a function of the restricted or atypical sample. For example, a researcher who finds a disproportionate number of feminine-typed males among alcoholics in a Veterans Administration hospital may draw conclusions about sex typing and substance abuse that are sample related rather than syndrome specific.

Inadequate or unrepresentative samples present two additional problems in drawing generalizations from the obtained sex-role data. Although statistical requirements may frequently be met by small sampling procedures,

application to larger populations is questionable. For example, suppose the researcher wishes to examine the effects of counselor gender and sex type on counselor and client behavior during assertion training. If only one counselor from each gender and sex-role category is used, the outcome is particularly vulnerable to unreliable conclusions.

Sampling problems also appear in the selection of control or comparison groups. Research designs that cut across age ranges, such as in developmental comparisons, are singularly sensitive to differences in cohorts, socioeconomic class, parental education, cultural milieu, and achievement or ability factors. Unrepresentative samples are easy to find. Take any set of high school juniors and compare them on a sex-role measure to groups of college and graduate students. Developmental hypotheses such as age or generation effects cannot be adequately tested between these sets of subjects unless each relevant external factor is accounted for, controlled, or covaried statistically. Socioeconomic factors may likewise differentiate an experimental from a normal control group. If a researcher wishes to examine psychological sex roles of girls with unplanned pregnancies who are now living in a home for unwed mothers, what is an appropriate comparison population?

Criteria for the selection of contrast or control groups are frequently unclear or gratuitous. The appearance of new ways to measure sex typing has encouraged the application of these scales to diverse populations that vary along unknown dimensions. Certainly, when contrast groups are used to demonstrate the discriminant validity of a sex-role measure, considerable support should be marshaled for assuming that these groups differ in sex-type orientation. Are all women who choose not to work feminine sex typed and all policemen masculine sex typed? If a validation study finds no difference in sex-role endorsement between these two groups, where does the fault lie? Is the test not valid, or are the groups unrepresentative of each sex type?

The foregoing comments are not meant to underestimate the difficulties in obtaining appropriate comparison groups for various populations. Simple suggestions about how to avoid sampling problems will necessarily leave

many issues untouched. However, consistent attention at least to the four criteria outlined above would be a welcome start.

Construct and Test Validation Procedures

Four major criteria for test and construct validity appear in the research literature: (a) self-report; (b) interpersonal perception and attribution; (c) task and situational performance; and (d) contrast populations. Since contrast populations were considered in the previous section, they will not be covered again. For purposes of brevity, both construct and test validation procedures will be considered together. However, it is important to point out that scale and construct validation do not always involve converging procedures (Fiske, 1971; Wiggins, 1973). Establishing the validity of the BSRI should be a less exhaustive procedure than considering the theoretical and conceptual domains encompassed by the construct of androgyny. For example, the inter-scale correlations among the four sex-role scales discussed above range from .61 to .81 for masculinity and from .51 to .73 for femininity (Kelly, Furman, & Young, in press). These correlations shrink by 52%–58% when the same correlations are computed for dichotomized scores (above and below the median). Although each scale is designed to measure some aspect of androgyny, it is clear that they overlap only partially and may be assessing somewhat differing conceptual and content domains. Consequently, the predictive validity of each scale needs to be assessed individually and independently of the scale validity of the remaining measures. Nevertheless, the following discussion will cover criterion variables as they apply both to the validity of specific tests and to the construct validity of androgyny, recognizing that some comments may apply differentially to each.

Self-report studies are by far the most popular method of demonstrating test or construct validity for androgyny. Self-report is obviously quick and economical, and it has face validity. Self-report methods base their strength on the belief that persons are their own best observers (Mischel, 1968; Mischel, Note 2). Problems arise with self-descriptive measures in androgyny research when these

scales are (a) insufficiently described; (b) marginally related to scales previously used to measure a similar construct; (c) dubiously related to the construct of androgyny or to the domain of sex typing; (d) unpublished, unvalidated, and possibly unreliable; or (e) in violation of the separation of gender and sex typing. When any of these shortcomings appear, questions can be raised about the significance of the data reported using self-report measures. Scales with unknown psychometric properties are particularly vulnerable when negative results are obtained. If the investigator finds no relationship between androgyny scores on the PAQ and "a scale especially contrived to measure openness to experience," is androgyny theory at fault, is the PAQ not predictive of "openness," or do we have an invalid criterion? A further problem in restricting the measurement of dependent variables to self-report is the introduction of substantial "method variance" (Campbell & Fiske, 1959). For example, to what extent does the obtained positive correlation between masculine and androgynous sex types and measures of self-esteem reflect the tendency of these people to endorse a high degree of many positive traits?

Despite their shortcomings under certain circumstances, self-report measures of dependent variables are not likely to disappear from use. Therefore, investigators who use self-report scales can refine their approach by considering one or all of the following: (a) Give preference to scales that have been used previously in similar research; (b) describe the scales used in sufficient detail to inform the reader of relevant psychometric characteristics of the scale and its previous use in similar contexts; (c) provide a theory or rationale for use of these particular scales, including their relationship to other scales that have been used to measure the same construct (such as feminism or need for achievement); and (d) develop directional hypotheses about the probable relationship between measures of sex typing and the variables presumably tapped by other self-report measures. Progress in sex-role theory depends on a body of reliable and comparable research. New data are meaningless unless they can be fitted into a matrix of accumulated knowledge. When di-

vergencies do occur, it is the task of the researcher to support the use of particular measures and to indicate their relationship to existing methods.

Interpersonal ratings and attributions represent a second area of validation research. Studies using this approach generally fall into one of two categories: (a) Subjects rate selected others on sex-typed characteristics to obtain stereotypes or (b) clinical analogues are constructed in which subjects evaluate written, visual, or auditory material about standard stimulus persons who appear in several sex-typed roles. The most popular variation of stereotype ratings has been to attempt to replicate the study by Broverman, Broverman, Clarkson, Rosenkrantz, and Vogel (1970), mainly to demonstrate negative outcomes. A common difficulty in replication of sex-role stereotype studies is neglect to repeat exactly the procedures and instructions used by the earlier studies. For example, in a single study, researchers change the target person from adult to child, the raters from clinicians to child-care workers, the instructions from "healthy" to "ideal," the scoring procedures from seven to two rating categories, and they shorten the number of items in the scale. Although this type of study may have utility for some purposes, it is clearly not a proper replication of Broverman et al.

A more appropriate application of replication procedures might be systematically to vary each factor that could contribute to the total variance in stereotyped attributions. In this manner, perhaps the researcher could substantiate a hypothesis that previous results are a function of instructions, item format, scoring criteria, or a sampled population. For example, should a researcher seriously wish to examine stereotyping in differing populations, it would be useful to obtain more than one contrast group. Thus, to show that teachers do or do not hold these stereotypes is probably not exciting enough to make a worm turn these days. However, it might be interesting to determine stereotyping differences among groups that vary along a particular dimension such as education, employment, administrative power, and so forth, especially when the chosen dimension has implications for institutional or administrative change.

Clinical analogues in which standard stimulus persons are given diagnoses, labels, or prescriptions for behavior change have crept into sex-role research. Since analysis of analogue research is beyond the scope of this article, comments will be limited to sex-role implications. A typical study runs like this: Subjects, usually undergraduates, are given a standard personality description and are asked to provide a diagnosis, recommend treatment, or make predictions about marital adjustment. Sex roles enter into the design when stimulus persons vary on gender and sex-role-appropriate or sex-role-inappropriate behaviors. Suppose the outcome of this design shows that male and female stimulus persons who use sex-role-reversed behaviors are judged as more seriously ill, more in need of treatment, and less likely to be happy in marriage. What are the problems here? First, generalization about current diagnostic and treatment practices from college sophomores to practicing clinicians is questionable. Do judgments on a two-paragraph written description replicate referral behavior in clinical situations in which multiple sources of information are available and when economics and family relationships are involved? Second, sex-role implications for each stimulus person may be unequal. When John runs sobbing into the bedroom after a marital quarrel, is this equal in social value to Mary who tuned up the family car in preference to going out for lunch with her friends? Problems in task equivalence appear in performance studies as well as in attribution or analogue studies. In either case, it is necessary to equate, by means of observer agreement, the sex-role relevance of the task or situation and its social value (degree of positive or negative valence). In the absence of this information, we cannot conclude that sex-role inversions lead to dire social consequences.

Two related areas of attribution research involving sex roles center on achievement variables: fear of success and achievement motivation attributions. The issues related to these topics are far too complex to consider here, but a number of recent reviews are available (see Frieze, 1975; Stein & Bailey, 1973; Tresemer, 1976; Zuckerman & Wheeler, 1975). It should be noted, however, that many

of the same problems occur in all of these attribution areas: task variables, expectancy for and the value of success, and external validity.

Task performance and behavior samples represent the most direct external validation procedures in sex-role research. Aside from what people tell us they do or prefer, or what others judge them to be, how do sex-typed or androgynous persons actually behave in sample situations? Although there are many problems involved in making behavioral predictions from self-reported characteristics (Fiske, 1971; Mischel, 1968; Spence & Helmreich, 1978; Mischel, Note 2; Spence, Note 3), behavior samples are essential to sex-role validation research. Androgynous orientations should predict greater adaptive or effective behavior across situations designed to elicit behaviors in the instrumental or expressive domains (Bem, 1974, 1975). Persons who describe themselves in few sex-typed terms might be expected to show behavioral deficits equally across sex-role correlated situations (Kelly, O'Brien, Phillips, Hosford, & Kingsinger, Note 4). Individuals who score high on either instrumental or expressive domains might be expected to show competence on sex-typed tasks relevant to expressive and instrumental domains and to exhibit behavioral inhibition or deficits on similar sex-reversed tasks.

Clearly, the conceptual and experimental challenge here is to construct tasks and situations that match the theoretical predictions. The two most common problems appear to be (a) criterion or construct validity: Is the selected situation congruent with the construct? Does the task represent a reasonable and logical extension of the construct domain to be examined (e.g., conformity, competitiveness, nurturance, risk taking)? and (b) sex-role validity: Does the task represent a logical sample of sex-role behavior within the domains assessed by the particular sex-typing measure? Issues in the general criterion validity of tasks are common to all research (Fiske, 1971) and will be omitted here. Sex-role validity of tasks has been considered only recently in the literature (Stein & Bailey, 1973) and is still problematic in current research efforts. One conceptual challenge con-

task selection is to delineate the probable domains of observable behaviors encompassed by the instrumental and expressive dimensions. To my knowledge, none of the current sex-role scales was designed to measure all of the traits that discriminate males from females or to differentiate all sex-typed cultural traits. When predictions to external behavioral situations extend beyond the conceptual network of the assessment instrument, low or negligible results can be expected.

The experimental challenge involves, among other things, careful attention to task selection for the behavioral validation of sex-role measures. Considerations should include adequate pretesting of tasks for sex-role endorsement; the value of the tasks for the participants; and the expectancy for success on the tasks, equated across sex-role or gender groups. In many studies, no information is provided on how the tasks were chosen. The resulting tasks may be gender typed, sex role typed, or only tangentially related to either of these variables. For example, when examining sex typing on the choice of luck or skill games, an electronic ball game may not be the most neutral task. It probably elicits both value and expectancy differences among groups. Any conclusions that are drawn about tendencies of sex-typed or androgynous persons to prefer skill or luck tasks are immediately biased by the nature of the activity.

If current sex-role measures are to receive a fair trial, pretest procedures should clearly differentiate tasks according to a sociocultural and sex-role definition (what is more desirable, typical, appropriate, etc.), rather than by gender discrimination (what differentiates males from females). Although gender selection may be used to demonstrate gender typing once the tasks are chosen, it seems appropriate to restrict the final task selection to a cultural judgment criterion. Comparisons between these two procedures may show that the basis on which any set of tasks is chosen has no appreciable effect on the data. However, this comparison is seldom attempted. Meanwhile, many researchers continue to contaminate gender and sex roles in design and task selection, thereby confusing and masking the contributions of each.

A summary of current practices in the vali-

dation of sex-role measures reveals a number of design problems that may render the results uninterpretable. In all three areas reviewed here—self-report, attributions, and behavior samples—procedural difficulties appear that are potentially avoidable.

Psychometric and Statistical Considerations

Discrepant approaches to data analysis are not limited to sex-role research. However, certain procedures are sufficiently problematic and common that they merit a brief commentary. Two topics will be considered; scoring for androgyny and statistical treatment of data.

Scoring procedures that are problematic fall into three categories: (a) failure to report how scales were scored or to report mean scale scores (A study reports the number of sex-typed and androgynous subjects but does not explain how these categories were obtained.); (b) idiosyncratic scoring systems that do not demonstrate the effects of these changes on the data (Researcher figures up a new way to calculate androgyny and reports only resulting data, without comparison to previous scoring criteria.); (c) misuse of androgyny scores indicating some misunderstanding of their meaning. (Study reports that one group was twice as androgynous as the other, based on the absolute differences between the androgyny scores.) Any one of these scoring practices prevents the reader from relating the present research to previous findings. New scoring procedures may be extremely useful, but their utility should be demonstrated by means of data-impact comparisons between the new and the traditional methods.

Statistical procedures deserve more than a passing nod. However, since many sex-role studies attempt to demonstrate group differences, a word of caution is justified. By far the most common annoyance is data analysis that treats each dependent variable separately, using individual *t* tests, chi-squares, one-way analyses of variance, or columns of single correlations. Aside from the opportunity to capitalize on chance variations, many dependent variables in personality research tend to be correlated. Single tests of significance cannot correct for the common variance in a group

of correlated measures. Many research studies would benefit from the use of multivariate procedures, and readers would benefit by encountering fewer dramatic results that fail to hold up under cross-validation.

Conclusions

The wealth of current research designed to evaluate the correlates and consequences of androgyny has been beset with multiple methodological problems. Many of the design and procedural difficulties that appear are common to other areas of virgin research. However, the current orthogonal conceptualization of sociocultural sex roles and their measurement by specific scales that meet this assumption introduce a number of methodological issues that are specific to androgyny investigations. As a function of Bem's unveiling of androgyny as a model of effective psychological functioning, validation studies have centered on the adjustment advantages of a relatively balanced, as compared to a sex-typed, sex-role endorsement. The resulting research efforts have produced some very creative solutions to the challenges of construct validation, as well as some repetitive and inconclusive approaches.

At the risk of oversimplification, one major design and conceptual problem centers around a diffusion and confusion between gender (male, female) and sex-role endorsement (masculine, feminine, androgynous). The distinction between these two variables is frequently ignored in the development of hypotheses, tasks, and tests. Even though Bem and her associates (Bem, 1975, 1976) have been careful to make this distinction clear, many others have not. The position was taken here that all components of androgyny research should differentiate cultural sex roles from gender typing. This consideration implies that theory, measurement of both independent and dependent variables, as well as reporting procedures, would benefit by respecting the sex role/gender distinction. Only in this manner can we tease out the relative contributions of sex-role advantages or drawbacks to males and females separately.

The limited research data accumulated so far suggest that sex roles emphasizing either

instrumental, expressive, or androgynous orientations may have differing implications for the psychological well-being of males and females in American culture (Bem & Lenney, 1976; Berzins et al., 1978; Jones et al., 1978; Kelly et al., 1977; Wiggins & Holzmuller, 1978). Although these group differences tend to favor the presence of moderately high masculinity scores (either alone or in a combined androgyny score), the adjustment advantages of masculinity are by no means universal and are tempered by the situation, the task, the measures used, and the gender of the experimenter. In a recent series of studies across a diversity of situations, Jones et al. (1978) found a number of Gender \times Sex Role interactions, with androgynous males showing more adjustive problems and both androgynous and masculine-typed females appearing more adaptive. The implication of these diverse findings is clearly to direct attention to refinements in research design, a specification of limiting conditions under which particular results can be expected to occur, and a continued careful distinction at all levels of research between sex-role and gender effects.

A second major issue relates to the psychometric definition of androgyny. At the present time, considerable disagreement exists concerning the appropriate method for translating raw scores on current sex-role scales into a predictive metric that is both statistically sound and psychologically meaningful. Two major scoring procedures are currently in use: Bem's original t ratio, which emphasizes an intraindividual subtractive balance definition of androgyny (Bem, 1974), and a median-split procedure, which includes the absolute numbers of masculinity and femininity item endorsements within a specified sample (Spence et al., 1975). Comparison of data using either of these two procedures suggests that under some conditions the two scoring methods produce equivalent results, and for other conditions the additive method yields new data (Bem, 1977; Berzins et al., 1978; Jones et al., 1978; Wiggins & Holzmuller, 1978). Some researchers have combined the two scoring approaches to produce a new metric based on both the relative and absolute scores (Babl, in press; Heilbrun & Pitman, Note 5). Still others have suggested the use

multiple regression analysis to take into account the full range of scores on both masculinity and femininity scales (Kelly et al., in press; Wakefield, Sasek, Friedman, & Bowles, 1976). With linear data, a multiple regression design might overcome some of the measurement limitations of current scoring methodologies. However, there do not appear to be any published data that examine the empirical implications of regression analysis for androgyny research. It is clear that some gains and losses accrue to each scoring procedure, and the issue is by no means closed. Hopefully, accumulated data will suggest which method yields a useful scoring procedure that will enable research from different laboratories to be compared. In the interim, it is suggested here that researchers specify carefully their scoring assumptions and procedures.

Regardless of the scoring scheme adopted, differences in measuring instruments will also contribute to variations in the androgyny validation theme. Although all four of the present scales assessing orthogonal sex roles and traits share a common variance, they are by no means interchangeable. It has been pointed out elsewhere (Kelly & Worell, 1977; Spence & Helmreich, 1978) that these scales all vary in assumptions about androgyny, item selection (origins of item pool, instructions to item raters, criteria for item inclusions, etc.), item content and format, and instructions to respondents (yes-no ratings on bipolar or unipolar choices). In addition, the masculinity and femininity scales show varying correlations with corresponding scales on each of the other tests, although the associations tend to be moderate to high. Moreover, when the same respondents fill out all four sex-role inventories, a large majority (61% when corrections are made for chance agreements) are categorized discrepantly by any pair of scales (Kelly et al., in press).

What these differences in scale characteristics and concordance imply for androgyny research is that generalizations concerning adjustment and psychological well-being should be confined to the particular instrument used to assess sex roles and the particular scoring methods adopted. None of the present scales is sufficiently calibrated so that predictions

from one scale can be transferred to another instrument. A recent study using matched predictions from the BSRI and the PRF ANDRO scales showed very little overlap on a set of dependent variables (Hicks, 1977).

A final issue concerns the extent to which the characteristics measured by any of these current sex-role scales reflect unitary traits or dispositions that are predictive of a wide range of behaviors, attitudes, and life-style choices. The limited data accumulated thus far strongly suggest that endorsement of one's typical degree of instrumental and expressive characteristics is not necessarily predictive of any or all sex-role and gender-correlated behavior. It should come as no surprise to anyone familiar with personality assessment that behavioral prediction from self-described personality traits is constrained by what one is willing and able to do in any particular situation. Self-attributions will thus interact situationally for each person with the value of an activity, expectancies for success, fear of failure, desires to please self and others, and real or perceived behavioral skill. Specific role-determined behaviors may not coexist with trait descriptions, because they vary on one or all of these limiting dimensions.

Of particular interest to androgyny traits is the question of the relative contribution of social competency to performance on sex-typed tasks. The behavioral activities selected to test androgyny hypotheses have included tasks that involve trait-related skills (such as positive and negative assertiveness), as well as role behaviors that require no skill but that may be differentially acceptable or aversive (e.g., diapering a baby, playing with a kitten). Future research should attempt to tease out the extent to which interpersonal skills and the positive and aversive stimulus values of criterion tasks interact with measures of sex-typed orientations. Although it is apparent that orthogonal sex-role measures are not indiscriminately predictive of varying indices of psychological well-being, direct behavioral tests must continue to be important criteria of what people are willing and able to do. As Mischel has aptly pointed out (Mischel, Note 2), situation-free personality variables hold little interest or utility for any psychologist.

Some Problems in Community Program Evaluation Research

Emory L. Cowen
University of Rochester

Realities of the community context militate against good program evaluation research. Many limiting factors in such research stem from a clash in values between those who must deliver and those who must evaluate community services. Detailed consideration is given to several clusters of difficulties that plague community program evaluation studies, including (a) sources of data bias, (b) issues of design, (c) problems in the choice and use of criteria, and (d) problems of experimental control. Although community program evaluation studies can surely be improved, it is unlikely that the purity of antiseptic, laboratory research will ever be attained. Ultimate conclusions about the effectiveness of community service programs may thus have to come about slowly and cumulatively, based on convergent findings from many individual less-than-ideal outcome studies.

The author is well qualified to write about research errors in community mental health because he has, personally, committed virtually every one of them. Had the editor told authors to start their article with a pithy folk wisdom that captured its essence, mine would have been: "Do as I say, not as I do!" This article is intended as a straightforward consideration of several hazards that plague community program evaluation research. It is *not* designed to lecture or to pontificate. If the words come through as "holier than thou," it will reflect a serious communication failure.

Starting this article as I did was dictated by other than modesty—or even masochism. It was to suggest that some problems of community research are so intrinsic to the nature of the beast that they are very difficult to surmount. As stated elsewhere (Cowen, Lorion, & Dorr, 1974), the choice for investigators in this field is often between doing far less than ideal research or no research at all.

With that as preamble, a first practical task

is to sharpen the article's focus—somewhat easier said than done. Terms such as community research or research in community psychology or mental health are broad and amorphous (Cowen, 1973). In an earlier article, I suggested that although clinical psychology, community mental health, and community psychology share common prime concerns with people's adjustment, adaptation, security, happiness, self-concept, that is, their well-being, the nature and timing of their defining practices differ radically (Cowen, 1977). Thus, clinical psychology—as well as psychiatry and social work—has traditionally used repair strategies such as psychotherapy addressed to already evident, crystallized problems. Community mental health's (CMH) roots lie in keenly felt dissatisfactions with the effectiveness of classic mental health repair systems. CMH does not abandon the casualty repair orientation; rather, it directs its efforts toward the perceived insufficiencies of past traditional approaches. The thrusts of the CMH movement are to identify problems earlier, in more natural settings (e.g., schools), and to use more flexible, hopefully more realistic approaches sometimes carried out by non-traditional help agents. The real importance of community in CMH is that it harbors settings and contexts that make it easier to do

My thanks to two anonymous, but gracious and constructive, referees who reviewed the initial draft. Their wisdom and perceptiveness is reflected in the current incarnation.

Requests for reprints should be sent to Emory L. Cowen, Department of Psychology, University of Rochester, Rochester, New York 14627.

these things. Community psychology, sharing much the same goals as traditional or CMH approaches, departs sharply from them in its strategies. It is mass oriented rather than individual oriented, and it seeks to build health from the start rather than to repair.

The preceding account is grossly oversimplified. It extracts distilled essences of pure models that are blurred and muddled, in nature, at many overlapping points. Moreover, the approaches are depicted unidimensionally when, in fact, each consists of an agglomerate of strategies, techniques and, ultimately, research terrains. Bloom (1977) documented that complexity for CMH, identifying 10 important ways in which such approaches differ from past traditional mental health practices. Of special interest to this discussion is Bloom's opening definition of CMH as "all activities undertaken in the community in the name of mental health" (1977, p. 49). In that vein, he cites as a first feature, which distinguishes CMH from traditional clinical activities, the fact that the former are based on *practice in the community*. Several of Bloom's later key discriminanda (e.g., emphases on early service delivery, indirect services, use of non-traditional manpower) are natural derivatives of the community locus of CMH programs.

Important as the preceding structural emphases are, they do not yet begin to identify CMH's substantive complexities. The latter can be illustrated simply by noting several of the field's active current areas of programming and research: needs assessment surveys; alcoholism and drug-abuse programs; mental health consultation by, and for, diverse groups; varied types of crisis intervention programs; selection, training, and performance of nontraditional help agents; informal help-giving processes, natural caregivers, and community support networks; early detection and intervention; and alternative service delivery modes for inner-city and rural folk.

A brief account such as this could not encompass the myriad of research problems of all the foregoing areas even if the author had (which he does not) the expertise to do so. That limitation, however, is more merciful than tragic. Though CMH evaluation research has clear defining qualities, it is not, thank goodness, a world unto itself with a totally

unique technology, methodology, and modus operandi. Its basic problems are related to those of other major areas of outcome research (e.g., evaluation of psychotherapy or educational programs).

The full array of research problems includes those of designing, conducting, and interpreting studies. The greatest commonality in such problems between outcome research in CMH and other areas—and thus the topic *least* pursued in this article—is error in interpreting findings. Thus, overinterpreting chance findings (e.g., the "meaning" of five F s out of 100 significant at $p \leq .05$); confusing statistical significance with meaningfulness in interpreting correlation coefficients (e.g., $r = .07$, significant at $p \leq .05$, because $N = 1,000$); capitalizing on chance to develop a regression equation that is not cross-validated; or overreacting to a significant chi-square based on small expected cell frequencies, unmodified by Yates's correction, are common errors of data interpretation in many substantive areas—not just CMH.

A key thesis of this article is that certain errors in designing and conducting CMH program evaluation studies flow naturally from the special hazards of *doing* research in the community. The latter include (a) the low priority that program evaluation research may have in an agency's hierarchy of values; (b) the researcher may be—or be *seen* as—a foreign body to the system; (c) the threat that evaluation research poses for a program's funding or personnel; (d) difficulties in gaining entry into community systems; (e) the complex research demands that longitudinal programs impose; (f) the vulnerability of community programs to change after they start; (g) the involvements of community review bodies; and (h) growing concerns about human rights and the invasion of privacy. Specific research problems considered later in this article can stem, directly or indirectly, from such qualities of community contexts. Accordingly, many gut problems of community research occur less because investigators do not "know any better" and more because reality keeps them from doing any better.

One key "common denominator" obstacle to sound community evaluation studies is that the researcher's and agency's goals frequently

work at cross-purposes. Schools are for teaching; courts are for meting out justice; community mental health center (CMHC) clinics are for working with patients, and hospital wards are to care for the sick. Community agencies share the mandate of bringing needed services to people. Their first concern must be with the extent and quality of those services. Their prime goal is to insure delivery of optimal services. The evaluator's first allegiance, by contrast, is to sound design, methodology, and instrumentation, which are so important to the defensibility of a study's conclusions. These perspectives can, and do, clash. The real rub comes when program personnel see the design of a prospective study as encroaching on, or restricting, services, and the researcher sees service pressures as a factor that will corrupt the study's integrity. To complicate the matter further, some service personnel see program evaluations as personal evaluations and, therefore, as threatening. Others, not sympathetic to research in the first place, or who feel harassed by heavy job pressures, resent the extra burdens that an evaluation study places on them.

Whether or not a just God in heaven might judge such perceptions to be warranted is not the critical issue. Because they are real to beholders, they result in very real behaviors such as lack of cooperation, anger, passive aggression, delayed and/or careless completion of forms in ways that limit their validity, and interpretability. There are few guaranteed solutions for such problems. Involving program personnel in planning studies, taking time to explain the purposes and significance of the research to them, using maximally parsimonious measures that insofar as possible, are relevant to the respondents' job turf, and feeding back findings in usable forms are steps that can strengthen program evaluation studies. But even so, the differing needs and values of program workers and evaluators remain as background noise that often works against sound research.

That less-than-idyllic backdrop frames consideration of specific problems in CMH program evaluation research in the sections to follow. Although not all of these problems fit neatly into pigeonholes, broad categories such as data and design bias, choice of criteria, and

the misuse of controls, clearly are chronic offenders.

Data Bias

In the past several decades, psychological research in general has become more sensitive to, and sophisticated about, sources of data bias. Observer judgments are highly subject to stylistic inputs such as social desirability, responding, "yeasaying" or "naysaying," excessive use or avoidance of extreme ratings, and halo effects, any of which can be confounded with substantive variables that an instrument purports to assess. Although ways of instrument construction and usage have been developed that minimize stylistic confounds (or, at least, identify them after the fact), the corrosive effects of those variables still mar community program evaluation studies. This is so because such studies often depend heavily on the judgments of service recipients and providers as prime data sources.

Few would disagree with the assertion that a client's view of how he/she has done in a program is *one* relevant way to evaluate the program's effectiveness. But there are many reasons why it is misleading to use such data as the *only* way of evaluating a program (Bloom, 1972). For brevity's sake, the issue can be put in concrete, caricatured form. When a program ends, the male client is asked, in 20 different guises: "So, how'd you do?" His response, also in 20 ways, is "Terrific!" Problem No. 1: Did he respond that way because that's how he feels or because he senses that that's what the experimenter wants to hear? Problem No. 2: If he truly *does* feel better, is it due to the program or because he just struck oil or won the Irish Sweepstakes? Problem No. 3: If indeed he does *feel* better because of the program, has his *behavior* changed in a parallel way?

Service providers are also relevant—indeed, important—data sources in program evaluation, because they are uniquely familiar with clients and their everyday behaviors. But they too are sources of potentially serious data bias. They can bias a study, obviously, by not completing essential forms, by completing them carelessly, or by submitting them too late. More subtly, their responses to questions

about client behavior and how it has changed can be shaped by their stake in, and cathexes to, a program, that is, whether they believe that they are *really* being asked to evaluate the client's behavior or their own effectiveness; whether they see the program as theirs or others' and, if the latter, whether they like or dislike those people.

The dilemma is clear. On the one hand, people who staff a program and/or receive its services have observations and information that are highly pertinent to its evaluation. But, for whatever reasons—many extraneous to the program's content and thrust—they do not always respond in those terms. The interpretability and ultimate contribution of rater judgments may be increased by broadening the observational report bases. There is more danger of bias, pro or con, with only one versus several judges or one versus several perspectives (e.g., self, therapist, job, home). If observers with different stakes and perspectives agree about change, it is more likely that real change has taken place. Even more useful, if feasible, is including behavioral anchor points in the overall evaluation net. Correspondences between bona fide behavior change and the judgments of human observers increase one's confidence in the latter as a converging source of evidence in evaluating program effects.

Design Problems

Campbell (1969) has written a sophisticated treatise on program evaluation designs for community research—a topic somewhat beyond the scope of this article. The present discussion focuses on two specific design issues that have created special problems for community research—follow-up and systematic versus representative design.

The purpose of follow-up is to insure that effects observed when a program ends accurately and stably mirror the program's impact. Follow-up data thus solidify generalizations about program effects over time. Such information is important for planning future programs. Immediate postprogram findings can be misleading in several respects. Thus, what seems to be improvement can dissipate over time, because it was not (a) real in the

first place, (b) solid enough to permit the individual to meet life's demands after the program ended, or (c) supported by the post-program environmental context.

Without follow-up, we can also underestimate program effects. Significant experimental-control differences may *not* be found when a program ends, but they may show up 6 months or a year later. Illustratively, a preventive program is developed for children experiencing current life crises who have not yet shown major signs of maladjustment. At the end of the program experimental subjects look much the same as comparable crisis (non-program) control subjects. When evaluated a year later, however, experimentals are found to have maintained sound adjustment, but nonprogram controls have deteriorated behaviorally and educationally. In such a situation one might infer that the program had important innoculative value but that it was too soon for that effect to be detected when the program ended. Without follow-up the community program evaluator is vulnerable to incorrect conclusions and generalizations. He/she may thus either perpetuate a shaky program or dismiss an effective one prematurely.

Brunswik (1947) wrote an informative essay on systematic and representative design in psychological experiments, later applied to research in clinical psychology (Hammond, 1954). Brunswik's main argument was that in order to generalize beyond a study's specific circumstances, one need not only have an adequate subject *N*, which most experiments do, but also experimental conditions that represent, statistically, the universe of circumstances to which the experimenter hopes to generalize.

A simple example would be a comparative study of the effects of male versus female examiners on operant conditioning rates of male and female subjects. Assume that such a study was done with one male and one female research assistant, each of whom ran 50 male and 50 female subjects, for a total of 200 subjects. Although, on the surface, that seems a "reasonable" *N*, the question is, reasonable for what? How useful is it to know that two particular experimenters—one of whom happened to be male and the other female—got different conditioning results either overall or

differentially by subjects' sex? Does such a finding mean that being a male or a female experimenter was *the* critical variable underlying the observed performance differences rather than, let's say, differences in their warmth, verbal styles, cues emitted, or degree of comfort with subjects? Most studies seek to generalize beyond their own literal conditions. For the hypothetical study cited, to generalize about the effects of male and female examiners would require representative sampling along the dimension of experimenter sex. Thus, in effect, the *N* for the study was not 200; it was 1 in each experimenter's group.

Community program evaluation studies are especially vulnerable to problems of systematic versus representative design. Such research often seeks to generalize about large community units (e.g., schools, CMHCs). The researcher, however, may have access to *one* or, at most, a very limited number of such units. Thus a study is conducted to learn how low-income subjects use mental health services within a CMHC and how effective those services are. The study, done at a large urban CMHC, involves a consecutive sample of 500 low-income subjects who sought services for whatever reasons, during the past *X* number of months. The study's main findings are that 54% of the subjects did *not* return after the initial visit and that short-term goal-oriented therapy was found (by whatever criteria) to be the most effective of four treatment conditions studied. Although such information may be very helpful in pinpointing the practices and strengths of the particular setting, a frequent error is to generalize the findings to CMHCs, or CMHCs in large urban settings. The problem in so doing is that the center in question has its own special defining qualities and practices (e.g., inviting/uninviting physical layout; poor/good reception and/or initial interviewing practices; and committed, dedicated short-term therapists), any of which can produce the specific findings obtained. To generalize about large CMHCs requires representative sampling on *that* dimension.

The problem comes up in many guises. An investigator might wish to compare the effectiveness of clinical case versus process consultation. Such a study is well designed in terms of the number and types of groups (e.g.,

teachers, lawyers, clergymen) with whom the approaches were used and the numbers of contacts with each group. However, if there is only one consultant per approach, generalization with respect to the study's main question is drastically restricted. Because there are so many ways (e.g., experience, comfort, and confidence with an approach; personal warmth; verbal facility) in which the consultants could have differed, besides the ostensible variable under study (i.e., *type of consulting approach*), conclusions about the relative effectiveness of the approaches could not be made without representative sampling on the consultant dimension.

Another example would be a comparative study of the attitudes and job satisfactions of mental health professionals and paraprofessionals. One convenient (often the most convenient) way of doing such a study is to recruit fairly sizable *N*s for both groups from a single, large facility that employs, let's say, 20 professionals and 40 paraprofessionals. Assume that the study is done that way and that clear group differences in job satisfaction are found. The investigator concludes that there are basic cross-group (mental health professionals vs. paraprofessionals) differences in job satisfaction. But, again, because the study was done in a single center, the findings are more likely to reflect that setting's particulars (e.g., hours or conditions of employment, salary levels, promotion policies, job security, how positions at various levels are perceived and valued) than *generalized* cross-group differences on the variable in question.

Generalization of research findings depends on representativeness of design on *all* pertinent dimensions. This cannot ordinarily be achieved in one variable systematic design. If a community program evaluation study seeks to reach conclusions that transcend a particular setting, it must adequately sample the situations and variables that are central to its generalization focus, as well as the usual adequate sampling of subjects.

Criterion Problems

The present discussion assumes that classic psychometric problems (e.g., reliability and validity) are well understood at least intel-

actually, and that researchers as well as editors do what they can to keep the faith with respect to them. Hence, this section focuses more particularly on criterion problems that are predisposed by the special nature and pressures of community research. Two such groups of problems are considered: (a) the extent to which criterion measures are appropriate to a study's purposes and (b) pressures on the researcher to use less than optimal criterion measures.

Are the criteria appropriate to the study's purposes? In considering how CMH approaches differ from traditional ones, one frequently noted characteristic is that they involve indirect rather than direct services (Bloom, 1977). Thus, we do consultation with public health nurses, pediatricians, teachers, and clergymen because these groups have extensive everyday contacts with distressed individuals. The rationale for consultation is that upgrading consultees' knowledge and skills helps them to be more effective in dealing with the personal problems that their clientele often bring to them.

Psychologically oriented educational programs for those who are about to become parents, or for the parents of newborn or young children, have a similar rationale. Hopefully, strengthening the knowledge and/or attitude bases of program participants can lead to more facilitating, health-producing child-rearing attitudes and practices. Thus, consultation and mental health education epitomize the structural pattern of indirect service; that is, they both are directed toward groups that have systematic contacts with and are hence in a position to help others. But the programs' *ultimate* concerns are with the beneficial effects that intermediaries have on target people.

Mental health consultation and education seek to enhance the knowledge, feelings, and attitudes of the groups that they touch. It is often assumed that if those variables change positively, constructive change in the behavior of people with whom the intermediary interacts will ensue. Because indirect service programs have direct contacts only with intermediaries, and because first-line changes are easier to get at than once-removed ones, measures of change in consultees or parents are

often used as the *only* basis for evaluating their effectiveness. Even if criterion measures are well selected at that level and convincing evidence of change is found (i.e., consultees or parents are shown to have *enjoyed* a program, *learned* a lot from it, and to have developed more favorable mental health *attitudes*), it cannot be assumed that those changes lead to more effective helping, or growth-supporting, practices.

Kelly (1971) addresses this issue:

The payoff from a consultation program is not only an alteration of the feeling states, belief systems, and aspirations of the consultee, but should also reflect a change in a person's relationships with those significant others who directly participate in his life setting. Therefore evaluation studies should not measure change in attitudes of consultees, nor analyze samples of the interactions between consultant and consultee, nor note changes in the consultee's self-concept, for such attempts at evaluation are not congruent with a conception of consultation as a preventive intervention. . . . If . . . consultation is effective in initiating a change process, then indices of effectiveness should be defined not only by changes in consultee performance, such as the classroom teacher, but by cumulative and successive changes in the behavior of significant others, for example, students in the classroom. . . . When considering research designs to document the effects of consultation . . . it is essential to provide for assessment of the radiating effects of the intervention. . . . An intervention such as consultation can be preventive only if the consultee produces change in significant others. (pp. 114-115)

The point to emphasize is that although there is nothing wrong per se with using waystation criteria such as changes in the knowledge and attitudes of consultees or parents in indirect service programs, such criteria alone are insufficient. So-called instrumental changes, if found, do *not* guarantee that positive behavior changes will follow in the ultimate target group. Without assessing the latter directly, there is the danger that all concerned parties will have had a pleasant, seemingly productive experience, that fails to help the program's ultimate targets.

Although the preceding is a widespread problem, it is not universal. Behavioral consultation (Heller & Monahan, 1977), for example, is often evaluated *only* in terms of specific behavior changes observed in ultimate targets. Moreover, there are examples of (non-behavioral) indirect service programs in par-

ent education (e.g., Hereford, 1963; Glide-well, Gildea, & Kaufman, 1973), in which positive program effects (behavioral and adaptive) were indeed shown for the intended *ultimate* targets—children. Research designs that include measures of changes both in direct recipients and ultimate targets offer an added dimension richness in that linkages between the two levels of change can be explored.

Pressures affecting the choice of criterion measures. Community background contextual factors, such as those discussed earlier, that interfere in general with program evaluation hit especially hard when it comes to selecting and using research criteria. If the basic climate is not conducive to evaluation, resistances to assessment procedures can, and do, develop. Such procedures can all too readily be seen as time-consuming, disruptive, and personally intrusive.

Time-consuming is often defined phenomenologically rather than objectively. The author has had the experience of finding respondents more receptive to a 1-page format that required 5 minutes to complete than to a similar 10-page format that required only 3 minutes to complete. That aside, the key practical concern is that if key responders see a measure as too time-consuming, for whatever reason, it can effectively rule out that measure as a criterion. Take the following example: The main objective of a day-care program is to "resocialize" patients along dimensions such as (a) initiative, (b) self-help behaviors, (c) interaction with peers, (d) interaction with program personnel, (e) outside recreational activities, and (f) outside job activities. The researcher thus believes that judgments by knowledgeable program personnel about changes in specific behaviors, in each of the above subareas, would be among the criteria of choice for the study. Although he/she develops an appropriate instrument to assess 10 specific behaviors per category that requires only 20 minutes per subject to complete, respondents decide they cannot, or will not, give that amount of time to the task. A frequent "compromise" solution in such circumstances is to use "quick and dirty" but vaguer and more abstract global ratings such as "interactions with peers." Although these may be useful, they also lose the richness of

the phenomena under the study, pull for generalized attitudinal responses to the program and its personnel, and narrow the base for evaluating specific program effects or identifying particular program strengths and weaknesses as a guide to its modification and improvement.

The reality bugaboo of the potential disruptiveness of evaluation procedures is another source of noise that materially restricts the researcher's choice of outcome criteria. One might, for example, envision several other data-gathering strategies for the hypothetical study just cited such as (a) direct behavioral observations of subjects to assess variables such as peer interaction, autonomy, initiative, and reactions to program personnel; and (b) tests that provide data from which inferences about such variables could be made. Both approaches present hazards. Apart from the intrinsic complexities involved in developing reliable, valid frameworks for observing and recording behaviors, such procedures are often seen as intrusive and are therefore resisted. "Outsiders" must be introduced to the doings of an ongoing program, a process that program personnel or participants may see as disruptive, threatening, uncomfortable, or just plain not wanted. Similarly, removing subjects from ongoing program activities (e.g., schoolwork) for evaluations, especially time-consuming ones, also elicits resistance—if not to stop the procedure entirely, then to pare it to the bone.

Sensitivity about potential invasion of privacy is another factor that restricts the use of certain criteria in evaluating community programs. A given program may seek to improve people's sexual adjustment; another may be aimed at solidifying disrupted parent-child relationships. But to probe directly in these sensitive (albeit face-valid) areas may be so threatening that the use of theoretically ideal criteria is blocked before the fact.

Zax and Klein (1960) argued that behavioral criteria are often among the best to use in evaluating the effectiveness of mental health interventions. Because behavior, and its disruption, often defines and is at the nerve center of an individual's problem, and because it tends to be objective and palpable, using behavioral indices of change, is both face valid and commonsensical. Unfortunately, the inac-

ability of such data, plus the fact that it may be costly or time-consuming to obtain, has caused it to be underused in evaluating the effectiveness of community programs.

The preceding constraints on the use of criteria put dire pressures on the community program evaluator to compromise. Compromise sometimes means using indirect measures; instruments that are out of phase with the program's goals; measures of unknown or dubious reliability and validity; and vague, global criteria that are difficult to relate to the study's focal variables. Though such problems are far from unique to community program evaluations, they are pronounced in that field. This is an especially tough blow, since variables of prime concern in CMH program evaluation research (e.g., health, pathology, adjustment, coping) are difficult enough to measure even when we have a "clean shot" at them (Bloom, 1977). Stated another way, program evaluation research is limited by the state of the art in assessment. Illustratively, the researcher may be asked to evaluate a program designed to strengthen the self-concepts of preschool children. If, however, a psychometrically sound measure of self-concept for children of that age is not available, the functional choice is between using an unsatisfactory measure of self-concept or a psychometrically more sound instrument that comes as close as possible to assessing that variable.

Special criterion problems come up in outcome studies that cut across groups or settings. Thus, in a study designed to compare the effects of a specific intervention on the attitudes, intellectual performance, and/or adjustment of middle- and low-income groups, it is important that the criterion measures be equally appropriate for the two groups being compared. If not, extraneous factors such as lack of item clarity or inappropriateness of test items for either group might easily be confounded with differential outcomes for the method being evaluated.

Much the same problem can occur in evaluation studies that cut across structurally comparable settings, which, however, use different assessment procedures. Cowen et al. (1974) have addressed this question in the context of a study designed to evaluate the ef-

fectiveness of a multidistrict school mental health program. Because the program was school based, an estimate of the child's current school performance seemed to be one reasonable criterion for evaluating its effectiveness. But going across school districts made it virtually impossible to obtain such a measure. Formerly, the classic "A, B, C, D, E" report card was an answer to the researcher's prayers precisely because it offered a nearly universal metric for evaluating current academic performance. But "them simplistic days" seem to be gone forever. The ancient grading system has been supplanted by a near infinity of variants—single, double and triple checks; red, blue, and green stars; or lions, tigers, and giraffes. Even more perplexing for the aspiring quantifier are the extensive free-prose reports used by many school districts these days to evaluate children. Such reports have been known to cover 20 or more pages and to be as much, or more, oriented to unfamiliar turf, such as identity problems, socialization skills, and self-concept as to the erstwhile, inviolable three Rs. However laudable efforts to find better, less competitive, less accusatory ways to assess a child's school performance are, they make it difficult, if not impossible, for researchers to use report card grades as a performance estimate in cross-district comparisons of program effects. Similar problems are encountered with educational achievement tests. School districts have become more and more individualized about which tests they use, for whom, and when such tests are given. Thus, in designs that cut across school districts, the experimenter may need to combine apples and bananas if he/she hopes to use performance and achievement data.

Such reality factors will continue to restrict the researcher's use of criterion measures. In addition, the intrinsic complexity of many community evaluation studies poses challenges in selecting criteria. Complexity means several things—*obvious* ones such as (a) the multicomponent nature of many community programs and (b) the fact that they seek to affect multiple functions—sometimes differently for different people—and *less than obvious* ones, such as the fact that they usually take place in specific contexts of cost, morale,

attitudes, and expectancies. Though it helps a great deal to know that a program "works," ultimately it is important to disaggregate component effects, separating active from inert ingredients and identifying differential program effects for participants with different characteristics. Because such information is critical for improving programs, criteria should be selected with those realities in mind.

Because programs have multivariate, differential, and changing outcomes, multiple outcome criteria, including behavioral ones wherever possible, should be used to evaluate them. Doing so not only accurately reflects a program's true complexity, but it also reduces the risk of putting all one's eggs in a single delicate criterion basket. Greater use should also be made of unobtrusive and/or unintended outcome measures; they are relatively easy to collect and potentially informative. Thus, an investigator might weep a bit less after finding that children in a school mental health program improved at $p < .09$, rather than $p < .05$, on a problem behavior inventory, were it also established that the principal had 30 fewer disciplinary referrals during the active program period. And, finally, in evaluation studies that require human judgments (by program personnel or target persons), pragmatic decisions to use brief, objective, and easy to understand and handle measures that are relevant to respondents' main interests and spheres of involvement can help the cause immeasurably.

Problems of control. Problems of control, like those of criteria, are basic to most areas of psychological research. Their uniqueness, if any, to community program evaluation research derives from the realities of the community context. Control, in evaluation studies, seeks to insure that changes in behavior and/or performance are due to the effects of the intervention, rather than to potentially confounding variables that can produce similar findings. Being cast as a control is basically a dull, unenviable fate. It commits the "victim" to all the "dirty work" of research (e.g., time loss, intrusiveness, disruptiveness) without direct "pay off"—characteristically defined as needed services. Small wonder that relatively few places jump through hoops to be controls. Since many settings (schools, hospitals, clin-

ics, courts) are unwilling to serve as controls under any circumstance, the theoretical pool of control groups is limited before the researcher ever gets to it.

Moreover, locating "any old" control group is hardly enough to assure a good outcome study. Ideally, experimentals and controls should be matched on a host of variables which, left unattended, could confound the findings. Although the exact nature of these variables depends on the program's nature and purposes as well as characteristics of the subjects, they often include age, sex, intelligence, race, socioeconomic status, and the nature and extent of preprogram maladjustment. Both because many settings eschew the control role and because experimentals and controls must be matched on many control variables, the experimenter may have few degrees of freedom in searching for appropriate community control groups. At the very least, it can be a vexing, time-consuming challenge.

Not surprisingly, then, many program evaluation studies are done without control groups. Such studies depend on within-group pre-post comparisons, which, though sometimes helpful, entail certain risks. For one thing, they do not control for spontaneous or natural change over time; for another, they rely heavily on human judgments of change—by subjects themselves or by program personnel—they are particularly susceptible to distortions such as response bias (Hawthorne, and reverse Hawthorne effects) (Zdep & Irvine, 1970). Still another danger of studies that lack controls is the tendency of initially extreme test scores to regress to the mean on readministration. Such natural regression on the surface, "looks like" improvement and can be confused with it. Finally, base rates for some behavioral criteria (e.g., delinquency rates and employment) that are appropriate in evaluating the effectiveness of certain programs change rapidly over short time periods (e.g., ages 12–14 for delinquency or 16–19 for employment). To use such criteria, without controls or anchoring base-rate data, could seriously distort a study's interpretation (Freeman & Sherwood, 1969).

Another community reality that undermines optimal control is the fact that experimental programs *must* often start at a certain time

and run for X period of time if they are to be evaluated at all. School-based programs, for example, are bounded by the beginning and end of the school year. The program must start when it must start, even if an adequate control group is not available. Following all due effort an approximately satisfactory control group may be located several months later. But, by then, children manifest different patterns of class adjustment problems (either because they are better known or due to normal seasonal variations), and class demographic structures have changed from what they were 2 months earlier. It is difficult to know, when experimentals and controls are assessed at different times of the year, whether scores on key criterion measures such as the preceding ones mean the same thing for the two groups.

Given the realities of the community research scene, many adaptations to, and "solutions" of, the control dilemma have been tried—some voluntarily, some otherwise. The own-control procedure, in which a group goes through an inert preprogram wait period, is designed to bypass the thorny problems of using matched controls. A variant of that approach is for a group to serve simultaneously as a matched control for an experimental group and as an own control for a specified time period, with the understanding that it will later participate in the regular program procedure. Although both of those variants may be useful, they may still present problems, for example, delay in providing services to individuals who need them or the dangers of systematically selecting as time controls subjects with less pressing service needs.

In some situations the most direct route to control is to subdivide a prospective pool of target subjects, within a given setting, into matched experimental and control subgroups. This approach is attractive both because it is convenient and because it may be easier to find a good overall match among within-setting subjects who share similar backgrounds, sociodemographic status, and histories. But there are also reasons why it may not work. Thus, if the program involves needed services, personnel from the setting may argue—sometimes vocally and insistently—that those with greatest need must have first call on ser-

vices. Withholding a promising service from someone who needs it badly to satisfy the niceties of an abstract research design simply will not fly. Indeed, if pushed too hard, it can sound the program's demise—either before it starts or through later noncooperation or active resistance. It takes no genius to imagine the public relations confusion that can ensue. The obvious point is that community research has a real, vital ecological surround—more so than almost any other area of psychological research. That surround must be taken into serious account at all stages.

Another factor that limits the usefulness of within-setting control is intrasetting communication about a program. If, for example, the program intervention involves the use of cotage parents to teach verbal mediational techniques of self-control to residential delinquent adolescents, there is the danger that training procedures and program practices will spill over from experimentals to controls in a given institutional setting. Many community intervention programs involve indirect services such as consultation. If teachers are targets of a consultation program, it is unrealistic to expect that they will apply newly learned skills only to experimental children in their class and *not* to controls, or that they will not discuss useful new discoveries with other (non-experimental) teachers in the building.

Control, as many investigators have learned, can be an elusive phenomenon; that is, "now you see it, now you don't." Seemingly pretty initial matches evaporate in the face of hazards beyond the experimenter's control. Thus an experimenter, who must start a program by a certain date, matches experimental and control groups on all major sociodemographic measures but not on preprogram adjustment or performance status. Because the latter data take longer to collect and score, the experimenter makes the perfectly reasonable assumption that random assignment of subjects will yield approximately matched groups on those dimensions. But it does not! Or, after careful matching is completed, attrition while the program is underway destroys the match. There are many reasons why such attrition occurs. People move, raters judges who furnished predata change jobs; administrative decisions are made to shift individuals out of

a program; needed data cannot be collected or prove to be invalid. And so it goes! If everyone who has been burned by such a problem submitted a brief description of his/her special headache, the resulting compilation of unanticipated, and "undeserved," false turns would fill many entire issues of this journal. After-the-fact loss of initial control for any of the preceding reasons is common, not rare, in community program outcome research. That is one reason why not all program evaluation studies *reported*—and even fewer of those *done*—ever "mess with" controls. Of those that do, a substantial number, present company included, have been victimized either by incomplete or far less than ideal initial control, or by unavoidable breakdown of control during the study.

Faced with such natural disasters, investigators who care about control have several compensatory options to pursue. One is to bail out, as best one can, statistically. Analysis of covariance is a generic procedure designed to minimize initial mismatches and to bring comparison groups back to approximately the same starting point. Another way to deal with initial mismatches is to hack and chisel at the subject groups in hopes of paring them down to approximately comparable samples. Among the dangers of this procedure is that the adjustments may have to be asymmetrical (either because the original disproportionality comes more from one group than from the other or because the N is more robust in one group than the other). If the reduction in N comes primarily from one group, it may distort the group's defining characteristics. Moreover, such a procedure often highlights an inherent conflict between the ideal of a tight match (which, necessarily entails loss of N) versus the robustness and representativeness of the samples retained. Since this conflict is real, it is sometimes resolved by tolerating noise in the match to preserve sufficiently large and representative N s for the major substantive program evaluation analyses.

An interesting but more subtle question that the researcher sometimes faces is, When is a control not a control? Thus, groups can be well matched statistically but not "psychologically." Take as an example a program in which crisis interventionists are trained to

use special abreactive techniques in which they have interest but no special investment. The experimental question is whether the use of such techniques improves intervention outcomes with people experiencing current life crises. The groups seen by the specially trained and "regular" workers are well matched demographically and in terms of the nature and seriousness of the crises that they have experienced. The study's criteria include the clinician's preratings and postratings of a series of relevant patient behaviors. In such a situation, experimental and control interventionists may have different cognitive sets about the study, with experimentals thinking that "they are evaluating the effectiveness of this new *program*" and controls believing that "they are evaluating *my* effectiveness as a clinician." If such differential program views exist, experimentals' postprogram ratings are more likely either to be objective or to reflect personal (pro or con) views of the *program*, whereas controls, who see *themselves* as the focus of the study, are more likely to provide positive change estimates for clients. Should that happen, genuine program effects are obscured or lost. A similar example can be cited in evaluating the effectiveness of school-based intervention programs. Teachers of experimental children in such programs are more likely than those of controls to see their behavioral evaluations of children as program-related. Hence, their judgments may be influenced by their views of, and attitudes toward, the program. By contrast, teachers of control children, lacking a program metric, are more likely to see the rating task in the context of how good a job *I* have personally done with Johnny or Mary this year. If so, there is a pull for them to give more positive end-of-year ratings (Cowen et al., 1974).

Standard statistical controls may also not suffice in situations in which a program's main content and activities happen, incidentally, to involve a major structural change in the everyday lives of the target subjects. Assume, for example, that college student volunteers are trained to work with chronic hospitalized patients using rational-emotive techniques. Is this sufficient in evaluating the effectiveness of the intervention to have a matched experimental and control group? Probably not! Such a de-

might confound the program's ostensibly active ingredient (i.e., the therapeutic approach) with the fact that the procedure, intentionally, involved establishing a meaningful interpersonal relationship with people whose lives ordinarily lacked such relationships. An ideal third group that would strengthen the study's interpretive base, is one that could control for the personal relationship (e.g., with games and recreational activities) in the absence of an intentional, therapy-system thrust. Similar examples can be identified for selective therapeutic programs with adolescents in correctional settings, children in institutions for the retarded, or geriatric patients.

The unusual complexity of certain community settings (e.g., hospitals and schools) plus the fact that many are veritable laboratories for exploring many, ever-changing, program variations underscores the fact that mere demographic-statistical comparability of experiments and controls does not automatically solve the control problem. From an experimenter's standpoint, evaluation of a specific program would be clearest if there were *no* other special programs in either the experimental or control settings. Indeed, experimenters' special blinders may impel them to see the world that way, even though that view does not correspond, ecologically, to reality. More often than not, settings such as schools and hospitals house a variety of programs—formal and informal and short- and long-lived. Some of these programs may address the same objectives and behaviors as the experimental program in question (Freeman & Sherwood, 1969). A behavior modification program for hospital patients may take place alongside of drug-therapy and patient ward-governance programs. A school mental health intervention may co-occur with Glasser circle and Distar programs (Cowen et al., 1974). The intermixing of such programs not only makes it difficult to evaluate their separate contributions but also often means that an ostensibly pure experimental program is in fact that program plus several overlapping services or programs in one setting, compared to another (so-called control) setting, which happens not to have that particular program but does have three or four other programs addressed to similar

behaviors in comparable target subjects. Sometimes, in fact, an administrative decision is made to assign the special program to one setting *because* (compared to other similar ones) it is deficient in the type of services that the program provides. Conversely, control settings may be assigned other similar programs as part of an (understandable) administrative philosophy of sharing the wealth. Practical problems of control, in such situations, are magnified by the facts that some of the overlapping programs, either in experimental or control settings or both, are likely to be short-lived or to change in the process, and new programs may be introduced while the experiment is in progress. Although each of the foregoing possibilities is regrettable experimentally, they are part of the community's reality.

Problems of proper control, in community research, are diabolically complex and create serious persistent stumbling blocks to sound program evaluation research.

Overview and Summary

Communities are many things. One thing they are not is an ideal laboratory for anti-septic psychological studies. Their extraordinary complexity, omnipresent flux, action-service orientation, and susceptibility to day-to-day pressures present real and formidable barriers to "Mr. Clean" program evaluation studies. These factors place major constraints on the design of studies, the types of criteria that can be used, and the rigor of sophistication of the control that can be exercised. Although some of those problems can be reduced through judicious planning, others, quite beyond the experimenter's control, cannot. This is one reason why theory, logic, and the actual development and implementation of new community programs have outpaced the field's supporting research base.

The tugs and pulls of this situation are clear. On the one side is the obvious need to pose important, socially significant questions and to understand the impact and value of innovative practices designed to overcome long-standing, refractory problems in mental health. On the other are our training and bloodlines as experimenters and our un-

derstandings of past accepted canons for accreting new knowledge. These opposing tensions are as apparent in community research as in any subdomain of psychology today.

The intent of this article is not to discourage trying harder. Such effort is sorely needed; it can have great payoff value. Much can be done to strengthen community program evaluation technology and to design studies that reduce sources of confound or error. Weaknesses in specific measures or in classes of criteria typically used in community program outcome research dictate that greater emphasis be placed on converging sources of evidence. But we must still expect that community realities will remain to militate against ideal research studies. The vulnerability of findings from any single community evaluation study points to the importance both of replication and of tolerance for a slow accretive process, in which small pieces in a puzzle gradually cumulate toward weight-of-evidence conclusions about major new programming approaches. Although such a process is not intrinsically inimical to the way of science, it may be more caricatured in community research than in other fields.

The compelling logic of the community approach, the significance of the problems it addresses, and the excitement and clinical promise of some of its early innovative programmatic efforts have been sufficient to carry the field's infancy and early childhood. The future, however, will stand or fall on the solidity of its empirical footing. Social significance cannot, in that process, be sacrificed at the altar of laboratory precision. Hence, we must expect that successive approximations—the gradual putting together of sometimes chipped or scarred building blocks—will be the way of community program evaluation research in the coming decades.

For the reader who seeks wisdom and sophistication beyond the frailties of the present account, the following additional sources are suggested: Schulberg, Sheldon, and Baker, 1969; Bloom, 1972; Roen, 1971; Glass, 1976; Hammer, Landsberg, and Neigher, 1976; Fairweather and Tornatzky, 1977; Neigher, Hammer, and Landsberg, 1977; and Guttentag and Saar, 1978.

Theoretical Risks and Tabular Asterisks: Sir Karl, Sir Ronald, and the Slow Progress of Soft Psychology

Paul E. Meehl
University of Minnesota

Theories in "soft" areas of psychology lack the cumulative character of scientific knowledge. They tend neither to be refuted nor corroborated, but instead merely fade away as people lose interest. Even though intrinsic subject matter difficulties (20 listed) contribute to this, the excessive reliance on significance testing is partly responsible, being a poor way of doing science. Karl Popper's approach, with modifications, would be prophylactic. Since the null hypothesis is quasi-always false, tables summarizing research in terms of patterns of "significant differences" are little more than complex, causally uninterpretable outcomes of statistical power functions. Multiple paths to estimating numerical point values ("consistency tests") are better, even if approximate with rough tolerances; and lacking this, ranges, orderings, second-order differences, curve peaks and valleys, and function forms should be used. Such methods are usual in developed sciences that seldom report statistical significance. Consistency tests of a conjectural taxometric model yielded 94% success with zero false negatives.

I had supposed that the title gave an easy tipoff to my topic, but some puzzled reactions by my Minnesota colleagues show otherwise, which heartens me because it suggests that what I am about to say is not trivial and universally known. The two knights are Sir Karl Raimund Popper (1959, 1962, 1972; Schilpp, 1974) and Sir Ronald Aylmer Fisher (1956, 1966, 1967), whose respective emphases on subjecting scientific theories to grave danger of refutation (that's Sir Karl) and major reliance on tests of statistical significance (that's Sir Ronald) are, at least in current practice, not well integrated—perhaps even incompatible. If you have not been accus-

tomed to thinking about this incoherency, and my remarks lead you to do so (whether or not you end up agreeing with me), this article will have served its scholarly function.

I consider it unnecessary to persuade you that most so-called "theories" in the soft areas of psychology (clinical, counseling, social, personality, community, and school psychology) are scientifically unimpressive and technologically worthless. Documenting that statement would of course require a considerable amount of time, but you can quickly get the flavor by having a look at Braun (1966); Fiske (1974); Gergen (1973); Hogan, DeSoto, and Solano (1977); McGuire (1973); Meehl (1960/1973a, 1959/1973f); Mischel (1977); Schlenker (1974); Smith (1973); and Wiggins (1973). These are merely some high visible and forceful samples; I make no claim to bibliographic completeness on the large theme of "What's wrong with 'soft' psychology." A beautiful hatchet job, which in my opinion should be required reading for all PhD candidates, is by the sociologist Andreski (1972). Perhaps the easiest way to convince yourself is by scanning the literature of soft psychology over the last 30 years and noticing what

This article is based on a lecture delivered at the meeting of the American Psychological Association, Washington, D.C., September 1976, on the occasion of the author's receiving Division 12, Section 3's Distinguished Scientist Award. The research reported here was assisted by Grant MH 24224 from the National Institute of Mental Health and the University of Minnesota Psychiatry Research Fund. Completion of the article was aided by a James McKeen Cattell Fund sabbatical award.

happens to theories. Most of them suffer the fate that General MacArthur ascribed to old generals—They never die, they just slowly fade away. In the developed sciences, theories tend either to become widely accepted and built into the larger edifice of well-tested human knowledge or else they suffer destruction in the face of recalcitrant facts and are abandoned, perhaps regretfully as a “nice try.” But in fields like personology and social psychology, this seems not to happen. There is a period of enthusiasm about a new theory, a period of attempted application to several fact domains, a period of disillusionment as the negative data come in, a growing bafflement about inconsistent and unreplicable empirical results, multiple resort to ad hoc excuses, and then finally people just sort of lose interest in the thing and pursue other endeavors.

Since I do not want to step on toes lest my propaganda falls on deaf ears, I dare not mention what strike me as the most egregious contemporary examples, so let us go back to the late 1930s and early 1940s when I was a student. In those days we were talking about level of aspiration. You could not pick up a psychological journal—even the *Journal of Experimental Psychology*—without finding at least one and sometimes several articles on level of aspiration in schizophrenics, or in juvenile delinquents, or in Phi Beta Kappas, or whatever. It was supposed to be a great powerful theoretical construct that would explain all kinds of things about the human mind from psychopathology to politics. What happened to it? Well, I have looked into some of the recent textbooks of general psychology and have found that either they do not mention it at all—the very phrase is missing from the index—or if they do, it gets cursory treatment in a couple of sentences. There is no doubt something to the notion. We all agree (from common sense) that people differ in what they demand or expect of themselves, and that this probably has something to do, sometimes, with their performance. But it did not get integrated into the total nomological network, nor did it get clearly liquidated as a nothing concept. It did not get killed or resurrected or transformed or solidified; it just kind of dried up and blew away, and we no longer wanted to talk about it or do experi-

mental research on it. A more recent example is the theory of “risky shift,” about which Cartwright (1973) wrote, after reviewing 196 papers that appeared in the 1960s:

As time went by . . . it gradually became clear that the cumulative impact of these findings was quite different from what had been expected by those who produced them. Instead of providing an explanation of why “groups are riskier than individuals,” they in fact cast serious doubt on the validity of the proposition itself (p. 225).

It is now evident that the persistent search for an explanation of “the risky shift” was misdirected and that any adequate theory will have to account for a much more complicated set of data than originally anticipated. But it is not clear how theorizing should proceed, since serious questions have been raised as to whether, or in what way, “risk” is involved in the effects to be explained (p. 226).

After 10 years of research, [the] original problem remains unsolved. We still do not know how the risk-taking behavior of “real-life” groups compares with that of individuals (p. 231).

I do not think that there is any dispute about this matter among psychologists familiar with the history of the other sciences. It is simply a sad fact that in soft psychology theories rise and decline, come and go, more as a function of baffled boredom than anything else; and the enterprise shows a disturbing absence of that *cumulative* character that is so impressive in disciplines like astronomy, molecular biology, and genetics.

There are some solid substantive reasons for this that I will list here, lest you think that I am beating up on the profession, unaware of the terrible intrinsic difficulty of our subject matter. Since (in 10 minutes of superficial thought) I easily came up with 20 features that make human psychology hard to scientize, I invite you to pick your own favorites. Differences as to which difficulties are emphasized will not, I am sure, cause any disagreement about the general fact. This is not the place to develop in detail the thesis that the human mind is hard to scientize, let alone to prove it. Each of the 20 difficulties is, I am aware, debatable; and one could find competent psychologists who would either deny a difficulty's reality—at least in the form I state it—or who, although admitting it exists, would maintain that we have, or will be able

to develop shortly, methods adequate to overcome or circumvent it. Each of these alleged difficulties in scientizing the human mind is sufficiently controversial to deserve a methodological article by itself. This being so, to substitute a once-over lightly (and hence inevitably dogmatic) defense of each as a real difficulty is, for those who accept it, a work of supererogation, and for the others, it is doomed to failure. I therefore confine myself to listing and explaining the problems, repeating that my purpose in so doing is to prevent the rest of my article from being taken as a kind of malicious and unsympathetic attack on psychologists (of which, after all, I *am* one!) based on an inadequate appreciation of the terrible difficulties under which we work. In a few cases I have explained at some length and replied to objections, these being cases in which a difficulty is not widely recognized in our profession or in which it is generally held to have been disposed of by a familiar (but erroneous) refutation or solution. Regrettably, some psychologists use "philosophical" arguments that are a generation or more out of date.

Since I am listing and summarizing rather than developing or proving, it seems appropriate to present the set of difficulties as follows:

1. *Response-Class Problem*

This involves the well-known difficulties of slicing up the raw behavioral flux into meaningful intervals identified by causally relevant attributes on the response side, a problem that exists already in the Skinner box (Skinner, 1938, p. 70), worsens in field study by an ethologist, and reaches almost unmanageable proportions in studying human social behavior of the kind to which clinical, social, and personality psychologists must address themselves (see, e.g., MacCorquodale & Meehl, 1954, pp. 218-231, after a quarter century still considered by some as best statement of the problem; Hinde, 1970, pp. 10-13; Meehl, 1954, pp. 40-44 and chap. 6 *passim*; Skinner, 1938, pp. 33-43).

2. *Situation-Taxonomy Problem*

As is well-known, the importance of an adequate classification and sampling of environ-

ments and situations has received less attention than Problem 1, above, despite emphasis by several major contributors such as Roger Barker (1968), Egon Brunswik (1955), and Saul B. Sells (1963). It seems likely that the problems of characterizing the stimulus side, even though often neglected by the profession or dealt with superficially, are about as intractable as the characterization of the response class. It is not even clear whether identification and measurement of the relevant stimulus dimensions (e.g., size) is the same task as concocting a taxonomy of "situations" and "environments," nor whether the answer to this question would quickly generate rules for an adequate statistical ecology applicable to research design. So I am perhaps lumping under this "situation-taxonomy" rubric three distinguishable but related problems. I am inclined to think that most (not all) of the current methodological controversy concerning traits versus situations is logically and mathematically reducible to this and the preceding category, since I think that traits are disposition clusters, and dispositions always involve at least implicit reference to the stimulus side; but this is not the place to push that view.

3. *Unit of Measurement*

One sometimes hears this conflated with one or both of the preceding, but, of course, it is not the same. There are questions in rating scales and in psychometrics (as well as in certain branches of nondifferential psychology) in which disagreements persist about such fundamental matters as the necessity of a genuine interval or ratio scale for the use of certain kinds of sampling statistical inference.

4. *Individual Differences*

Perhaps the shortest way to discuss this one is to point out the oddity that what is one psychologist's subject matter is another psychologist's error term (Cronbach, 1957)! More generally, the fact is that organisms differ not only with respect to the strengths of various dispositions, but, more common and more distressing for the researcher, they differ as to *how* their dispositions are shaped and

organized. As a result, the individual differences involved in "mental chemistry" are tougher to deal with than, say, the fact that different elements have different atomic numbers or that elements with the same atomic number vary in atomic weights (isotopes).

5. Polygenic Heredity

It is generally conceded that the measurement and causal inference problems that arise in biometrical genetics are, with some exceptions, more difficult than those found in the kind of single factor dominant or recessive gene situation on which the science of genetics was originally founded. Except for Mendelizing mental deficiencies and perhaps some psychiatric disorders that are transmitted in a Mendelizing fashion, most of the attributes studied by soft-field psychologists are influenced by polygenic systems. Usually we must assume that several totally different and unrelated polygenic systems influence a manifest trait like social introversion. Introversion may be based in part on a unitary (although polygenic) variable, as shown by Gottesman (1963) and others. However, as an acquired disposition of the adult-acclimated individual, it presumably results from a confluence of different polygenic contributors such as basic anxiety readiness, mesomorphic toughness, garden-variety social introversion, dominance, need for affiliation, and the like.

6. Divergent Causality

As pointed out 35 years ago by the physical chemist Irving Langmuir (1943; London, 1946; Meehl, 1954, pp. 60-61; Meehl, 1967/1970b, especially Footnotes 1-8 on pp. 395-396), there are complex systems whose causal structure and boundary conditions are such that slight differences—including those that are, for practical predictive and explanatory purposes, effectively "random" (whatever their inner deterministic nature may be)—tend to "wash out," "cancel each other," or "balance" over the long run. On the other hand, there are other systems in which such slight perturbations or differences in the exact character of the initial conditions are, so to speak, amplified over the long run. Langmuir christened

the former kind of causality as "convergent," as when we say that the average errors in making repeated measurements of a table length tend to cancel out and leave us with a stable and highly trustworthy mean value of the result. On the other hand, an object in unstable equilibrium can lean slightly toward the right instead of the left, as a result of which a deadly avalanche occurs burying a whole village. Although both sorts of systems are found at all levels of Comte's Pyramid of the Sciences, it seems regrettably true that the incidence of important and pervasive types of divergent causality is greater in the sciences of behavior.

7. Idiographic Problem

It is not necessary to "settle" the long-continued methodological controversies regarding idiographic versus nomothetic methods in psychology and history (e.g., whether they are philosophically, metaphysically fundamentally different) to agree with strong proponents of the idiographic method, such as Gordon Allport (Allport, 1937) or my long-time friendly adversary on the prediction issue, Robert R. Holt (1958), that the human personality—unless one approaches it with the postulate of impoverished reality—has in its content, structure, and, conceivably, even in individual differences as to some of its "laws," and very much in its origins, properties and relations that make the study of personality rather more similar to such disciplines as history, archeology (historical), geology, or the reconstruction of a criminal case from police evidence than the derivation of the molar gas laws from the kinetic theory of heat or the mechanisms of heredity from molecular biology. Some would argue that such explanatory derivations aside, even the mere inductive subsumption of particulars (episodes, molar traits, persons) under descriptive generalizations is a more difficult and problematic affair in these disciplines than in most branches of physical and biological science.

8. Unknown Critical Events

Related to divergent causality and idiographic understanding but distinguishable

from them is the fact that critical events in the history of personality development are frequently hard to ascertain. There is reason to believe that in some instances they are literally never ascertained by us or known to the individual under study, even somebody who has spent 500 hours on the analytic couch. They are sometimes observable events that, however, were not in fact observed and recorded, such as the precise tone of voice and facial expression that a patient's father had when he was reacting to an off-color joke that the patient innocently told at the dinner table at age 7. Every thoughtful clinician realizes that the standard life history that one finds in a medical chart is, from the standpoint of thorough causal comprehension, so thin and spotty and selective as to border on the ludicrous. But there is also what I would view as an important causal source of movement in one rather than another direction of divergent causality, namely, inner events, such as fantasies, resolutions, shifts in cognitive structure, that the patient may or may not report and that he or she may later be unable to recall.

9. Nuisance Variables

Other things equal, it is handy for research and theorizing if we can sort out the variables into three classes, namely, (a) variables that we manipulate (in the narrow sense of the word *experimental*), (b) variables that we do not manipulate but can hold constant or effectively exclude from influence by one or another means isolating the system under study, and (c) variables that are quasirandom with respect to the phenomena under study, so that they only contribute to measurement error or the standard deviation of a statistic. Unfortunately, there are systems, especially social and biological systems of the kind that clinical psychologists and personologists study, in which there is operative a nonnegligible class of variables that are not random but systematic, that exert a sizable influence, and are themselves also sizably influenced by other variables, either exogenous to the system (F. M. Fisher, 1966) or contained in it, such that we have to worry about the influence of these variables, but we cannot always ascertain the

direction of the causal arrow. Sometimes we cannot even get sufficiently trustworthy measurements of these variables so as to "partial out" or "correct" their influence even if we are willing to make conjectures about the direction of causality. There are some circumstances in which we can extrapolate from experimental studies or from well-corroborated theory to make a high-confidence decision about the direction of causal influence, but there are many other circumstances—in soft psychology, the preponderating ones—in which this is not possible. Further, lacking special configurations such as highly atypical cells in a multivariate space or correlation coefficients that impose strong constraints on a causal interpretation, or provisional assumptions as relied on in path analysis (Li, 1975), the system is statistically and causally indeterminate. (Why these constraints are regularly treated as "assumptions" instead of refutable conjectures is itself a deep and fascinating question that I plan to examine some other time.) The well-known difficulties in assessing the influence of socioeconomic status (SES) on children's IQ when unscrambling the hereditary and environmental contributors to intelligence is perhaps the most dramatic one, but other less emotion-laden examples can be found on all sides in the behavioral sciences. (See Meehl, 1970a, 1971/1973b).

10. Feedback Loops

A special case in engineering is the usual in psychology, that a person's behavior affects the behavior of other persons and hence alters the schedule imposed by the "social Skinner box." The complexities here are so refractory to quantitative decomposition that yoked box setups came to be used even for the (relatively simple) animal case as a factual substitute for piecewise causal-dispositional analysis. In the human social case, they may be devastating.

11. Autocatalytic Processes

The chemist is familiar under the label *autocatalysis* with a rare but important kind of preparation in which one of the end products of the chemical processes is itself capable of catalyzing the process. Numerous common ex-

examples spring to mind in psychology, such as anxiety and depression as affects or economic failure as a social impact. Much of neurosis is autocatalytic in the cognitive-affective-volitional system, as are counterneurotic healing processes. When this kind of complicated setup is conjoined with the critical event, idiographic, and divergent causality factors, and also with the individual differences factor (that parameters relating the growth of one state of schedule to a dependent variable, which itself in turn acts autocatalytically, show individual differences), the task of unscrambling such a situation becomes terribly difficult.

12. *Random Walk*

There is a widespread and understandable tendency to assume that the class of less-probable outcomes, given constancy of other classes of causally efficacious variables, should in principle be explicable by detecting a class of systematic input differences. Thus, for instance, we try to understand the genetic/environmental contributions to schizophrenia by studying discordant monozygotic twins. If I develop a florid clinical schizophrenia and my monozygotic twin remains sane and wins the Pulitzer Prize for poetry, it is a sensible strategy for the psychologist to consider my case *and similar cases* with an eye for "systematic differences" (such as who was born first, who was in what position in the uterus, or who had a severe case of scarlet fever with delirium) as responsible for dramatic difference in final outcomes. When one reflects on the rather meager yield of such assiduous ferretting out of systematic differences by, say Gottesman and Shields (1972) in their excellent book, one experiences bafflement. On the one hand, the concordance rate for monozygotic twins is only a little over 50%, indicating a very large nongenetic component in causality. Yet, on the other hand, we find feeble or null differences when we look at the list of "obvious, plausible" differentiators between the twins who fall ill and the twins who remain well. Of course, one can always say—and would no doubt be partly right in this—that we just have not been clever enough to hit on the right ones; or even if, qualitatively, they are the right ones, we do not have sufficiently

construct-valid measures of them to show up in the statistics.

There is, however, an alternative explanation that when one reflects on it, is plausible (at least to a clinical practitioner like myself) and that has analogues in organic medicine and in other historical sciences like geology or the theory of evolution, to wit, that we are mistaken to look for a "big systematic variable" of the kind that is already in our standard list of influences, such as organic disease, parental preference, or SES of an adoptive home. Rather, we might emphasize that a human being's life history involves as one form of divergent causality, something akin to the stochastic process known as a "random walk" (Bartlett, 1955, pp. 15–20, 47–50, 89–96; Feller, 1957, pp. 73, 311; Kemeny, Snell, & Thompson, 1957, pp. 171–177; Read, 1972, pp. 779–782). At several points that are individually minor but collectively critical determinative, it is an almost "chance" affair whether the patient does A or not A, whether his girl friend says she will or will not go out with him on a certain evening, or whether he happens to hit it off with the ophthalmologist that he consults about some peculiar vision disturbances that are making him anxious about becoming blind, and the like. If one twin becomes psychotic at the end of such a random walk, it is possible that he was suffering from what was only, so to speak, "bad luck"—not a concept that appears in any standard list of biological and social nuisance variables!

Luck is one of the most important contributors to individual differences in human suffering, satisfaction, illness, achievement, and so forth, an embarrassingly "obvious" point that social scientists readily forget (Gunther, 1977; Jencks, 1972, pp. 8–9, 227–228; Popper, 1974, pp. 36–37; Stoddard, 1929; for further discussion of this see Meehl, 1972/1973g, pp. 402–407, Meehl, 1973d, pp. 220–221). Of course, the fact that a process resembles a random walk does not mean that it is not susceptible to quantitative treatment. Witness the extensive formal development of this sort of process in the field of finite mathematics by engineers and others. The point is that its analytical treatment will not look like the familiar kind of search for a systematic class

of differentiating variables like SES as a nuisance variable in relationship to educational outcome and intelligence.

13. *Sheer Number of Variables*

I suppose that this is the most commonly mentioned of the difficulties of social science, and I assume that my readers would accept it without further elaboration. But it is worth mention that the number of variables is large from several different viewpoints. Thus we deal on one side with a *large number of phenotypic traits*, conceiving a phenotypic trait as a related family of response dispositions that (a) are correlated to some stipulated degree pairwise and that (b) have some kind of logical, semantic, social, or other "meaning" overlap or resemblance that entitles us to class them together. Or, again, we consider a large number of dimensions on the stimulus side and on the response side that are relevant in formulating a law of behavior acquisition, as well as in the subsequent control and activation dispositions thus acquired. From still another viewpoint, the list of historical causal influences is long and heterogeneous, ranging from such diverse factors as a mutated gene or a never-diagnosed subclinical tuberculosis to a mother who mysteriously permitted herself the fantasy that a brutal father would go away, and the like. It should be noted that this matter of sheer number of variables would not be so important (except as a contributor to residual "random variation" in various kinds of outcomes) if they were each small contributors and independent, like the sources of error in the scattering of shots at a target in classical theory of errors. But in psychology this is not typically the situation. Rather, the variables, although large in number, are each nuisance variables that carry a significant amount of weight, interact with each other, and contribute to idiographic development via the divergent causal-ity mode.

14. *Importance of Cultural Factors*

This source of individual differences, both in acquired response clusters (traits) and in

the parameters of acquisition and activation functions, especially when taken together with the genetic factors contributing, for instance, to social competence, mental health, intellect, and so on, makes for unusual complications in understanding how somebody got to be the way he is. We are, for instance, so accustomed to referring to nuisance variables like SES in considering the design of experiments that involve SES-related individual differences that we readily forget something every reflective person knows—that the measures of things like SES are general and not tailor-made for what is idiographically more significant in the development of a particular person. So when we speak of "controlling for SES," that is a loose use of language in comparison with "controlling the temperature" in a Skinner box or controlling the efflux of calories in a physics lab by use of a bomb calorimeter. A treatise on the principles of internal medicine (such as Harrison et al., 1966) sometimes refers to cultural factors, including those that are not at all understood—in the way that, say, dietary deficiency might be mediated by extreme poverty in a backward country—and simply says that for some reason this disease is found more frequently among the rich than among the poor. But the *important* causal chains of prime interest to the physician, even in his role as an advisor of preventive medicine, do not typically involve worry about whether somebody is fifth-generation upper class or the third child of parents who became anxious after the birth of the second oldest sibling. However, this kind of consideration might be crucial in reconstructing the life history of such a person.

15. *Context-Dependent Stochastologicals*

Cronbach and Meehl (1955/1973) and subsequent writers adopted (from the neopositivist philosophers of science) the phrase *nomological network* to designate the system of lawlike relationships conjectured to hold between theoretical entities (states, structures, events, dispositions) and between theoretical entities and their observable indicators. The "network" metaphor is chosen to emphasize the structure of such systems, in which the *nodes* of the network, representing the postu-

lated theoretical entities, are connected by the *strands* of the network, representing the lawful relationships hypothesized to hold between the entities. What makes such a set of theoretical statements a system (rather than a mere conjunction of unrelated assertions, a "heap of hypotheses") is the semantic fact of their shared terms, an overlap in the propositions' inner components, without which, of course, no deductive fertility and no derivation chains to observational statements would be formally possible. The network is empirical (and "scientifically respectable"), because a proper subset of the theoretical terms is co-ordinated in fairly direct ways ("operationally") with terms designating perceptual or instrument-reading predicates. These latter predicates normally possess the admirable properties of *quick decision*, *minimal theory dependence*, and *high interpersonal consensus*.

Despite the current distaste for these "objectivist" conceptions, I remain an old-fashioned unreconstructed positivist to the limited extent that I think science—both "normal science" and "revolutionary, paradigm-replacing science"—differs from less promising, non-cumulative, and personalistic enterprises like politics, psychotherapy, folklore, ethics, metaphysics, aesthetics, and theology *in part* because of its skeptical insistence on reliable (intersubjective, replicable) protocols that describe observations. Skinner is in better shape than Freud partly because Norman Campbell (1920/1957, p. 29) was right in saying that the kinds of judgments for which universal assent can be obtained are (a) judgments of temporal simultaneity, consecutiveness, and "betweenness"; (b) judgments of coincidence and "betweenness" in space; and (c) judgments of number. I cannot view the increasingly fashionable dismissal of these objectivity-oriented views as other than obscurantist in tendency. (See Kordig, 1971, 1973.)

However, the nomological network, even though correlated directly, here and there, with observational data, is not "operational" throughout, since some of the nodes and strands are connected with the observational data base only via other subregions of the network. As Hempel said (1952):

A scientific theory might therefore be likened to a complex spatial network: Its terms are represented

by the knots, while the threads connecting the latter correspond, in part, to the definitions and, in part to the fundamental and derivative hypotheses included in the theory. The whole system floats, as it were, above the plane of observation and is anchored to it by rules of interpretation. These might be viewed as strings which are not part of the network but link certain points of the latter with specific places in the plane of observation. By virtue of those interpretive connections, the network can function as a scientific theory: From certain observational data, we may ascend, via an interpretive string, to some point in the theoretical network, thence proceed, via definitions and hypotheses, to other points, from which another interpretive string permits a descent to the plane of observation. (p. 36)

Even though the core of these ideas is sound and important, the word *nomological* is in soft psychology at best an extension of meaning and at worst a misleading corruption of the logician's terminology. Originally it designated strict laws as in W. E. Johnson's (1921/1964) earlier use of "nomic necessity" (p. 61). The lawlike relationships we have to work with in soft psychology are rarely (never?) of this strict kind, errors of measurement aside. Instead, they are correlations, tendencies, statistical clusterings, increments of probabilities, and altered stochastic dispositions. The ugly neologism *stochastological* (as analogue to *nomological*) is at least shorter than the usual "probabilistic relation" or "statistical dependence," so I shall adopt it. We are so accustomed to our immersion in a sea of stochastologicals that we may fail to notice what a terrible disadvantage this sort of probabilistic law network puts us under, both as to the clarity of our concepts and, more importantly, the testability of our theories. (One still hears the tiresome complaint that a theoretical system cannot be simultaneously concept definatory and factually assertive, despite repeated explanations of how this works. See, e.g., Braithwaite, 1960, pp. 76-87; Campbell, 1920/1957, pp. 119-158; Carnap, 1936-1937/1950, 1952/1956, 1966, pp. 225-226, 265-274; Feigl, 1956, pp. 17-19; Hempel, 1952, 1958, pp. 81-87; Lewis, 1970; Maxwell, 1961, 1962; Meehl, 1977, pp. 35-37; Nagel, 1961, pp. 87, 91-93; Pap, 1958, pp. 318-321, 1962, pp. 46-52; Popper, 1974, pp. 14-73; Ramsey, 1931/1960; Sellars, 1948.)

When the observational corroborators of the theory consist wholly of percentages, crude

curve fits, correlations, significance tests, and distribution overlaps, it is difficult or impossible to see clearly when a given batch of empirical data refutes a theory or even when two batches of data are (in any interesting sense) "inconsistent." All we can usually say with quasi-certainty is that context-dependent statistics should *not* be numerically identical in different studies of the same problem. (A dramatic recent example of this was the discovery that some of Sir Cyril Burt's correlation coefficients were *too consistent* to have been derived from the different tests and populations that he reported!)

In heading this section "Context-Dependent Stochastologicals," I mean to emphasize the aspect of this problem that seems to me most frustrating to our theoretical interests, namely, that the statistical dependencies we observe are always somewhat, and often strongly, dependent on the institution-cum-population setting in which the measurements were obtained. Lacking a "complete (causal) theory" of what influences what, *and how much*, we simply cannot compute expected numerical changes in stochastic dependencies when moving from one population or setting to another. Sometimes we cannot even rationally predict the direction of such changes. If the difference between two Pearson correlations were safely attributable to random sampling fluctuation alone, we could use the statistician's standard tools to decide whether Jones's study "fails to replicate" Smith's. But the usual situation is not one of simple cross-validation shrinkage (or "boostage")—rather, it involves the validity generalization problem. For this, there are no standard statistical procedures. We may be able, relying on strong theorems in general statistics plus a backlog of previous experience and a smattering of theory, to say some fairly safe things about restriction of range and the like. However, thoughtful theorists realize how little *quantitatively* we can say with sufficient confidence to warrant counting an unexpected shift in a stochastic quantity as a strong "discorroborator." This being so, we cannot fairly count an "in the ball park" predicted value as a strong corroborator. For example, Meehl's Mental Measure correlates .50 with SES in Duluth junior high school students, as predicted from Fis-

bee's theory of sociability. When Jones tries to replicate the finding on Chicano seniors in Tucson, he gets $r = .34$. Who can say anything theoretically cogent about this difference? Does any sane psychologist believe that one can do much more than shrug?

Although probability concepts (in the theory) and statistical distributions (in the data) sometimes appear in both classical and quantum physics, their usual rôle differs from that of context-dependent stochastologicals in social science. Without exceeding space limitations or my competence, let me briefly suggest some differences. When probabilities appear in physics and chemistry, they often drop out in the course of the derivation chain, yielding a quasi-nomological at its termination (e.g., derivation of gas laws or Graham's diffusion law from the kinetic theory of heat, in which the postulates are nomological, the "conditions" are probability distributions, and the resulting theorems are again nomological). Second, when the predicted observational result still contains statistical notions, their numerical values are either not context dependent or the context dependencies permit precise experimental manipulation. A statistical scatter function for photons or electrons can be finely tuned by altering a very limited number of experimental variables (e.g., wavelength, slit width, screen distance), and the law of large numbers assures that the expected "probabilistic" values of, say, photon incidence in a specified band will be indiscernibly different from the observed (finite but huge) numbers.

All this is very unlike the stochastologicals of soft psychology, in which strong context dependence prevails, but we do not know (a) the complete list of contextual influences, (b) the function form of context dependency for those influences that we can list, (c) the numerical values of parameters in those function forms that we know or guess, or (d) the values of the context variables if we are so fortunate as to get past Ignorances a-c. Finally, unlike physics, our sample sizes are usually such that the Bernoulli theorem does not guarantee a close fit between theoretical and observed frequencies—perhaps one of the few good uses for significance tests?

16. Open Concepts

As a consequence of the factors listed supra, especially those numbered 4, 7, 9, 15, it is usually not possible in the soft areas of social science to provide rigorous, explicit, or—the holy word when I was in graduate school—operational definitions for theoretical concepts. This difficulty occurs not because psychologists are intellectually lazy or sloppy, although most of us are at times (some routinely and on principle). Rather, it arises from the intrinsic nature of the subject matter, that is, from the organism's real compositional nature and structure and the causal texture of its environment. As has often been pointed out, one can concoct quick and easy "operational definitions" of psychological terms, but they will usually lack theoretical interest and, except for some important special cases (e.g., purely predictive task-tailored psychometrics and some kinds of operant behavior control), generalizable technological power (Lazarus, 1971; Loevinger, 1957). It is remarkable evidence of cultural lag in intellectual life that one can still find quite a few psychologists who are hooked on the dire necessity of strictly operational definitions, and who view open concepts as somehow methodologically sinful, although it is now a quarter of a century since the late Arthur Pap published his brilliant article on open concepts (Pap, 1953, see also chap. 11 of Pap, 1958). To do justice, and highlight the cultural lag, I should mention the related article of Waismann that antedated Pap's by 8 years (Waismann, 1945) and even Carnap's of 40 years ago (1936–1937/1950). I cannot name a single logician or a philosopher (or historian) of science who today defends strict operationism in the sense that some psychologists claim to believe in it. (They don't really—but you have to listen awhile to catch the deviations in *substance* when pseudooperationists are not discoursing dogmatically about *method*.)

The problem of open concepts and their relation to empirical falsifiability warrants a separate article, with which I am currently engaged, but suffice it to say here that the unavailability of open concepts in social and biological science tempts us to sidestep it by fake operationism on the one side (if we are

of the tough-minded, superscientific orientation) or to be contented with fuzzy verbalisms on the other side (if we are more artsy-craftsy or literary), thinking that it is the best we can get. The important point for methodology of psychology is that just as in statistics one can have a *reasonably precise theory of probable inference*, being "quasi-exact about the inherently inexact," so psychologists should learn to be sophisticated and rigorous in their metathinking about open concepts at the substantive level. I do not mean to suggest in saying this that the logicians' theory of open concepts is in a highly developed state, but it is far more developed than one would think from reading or listening to most psychologists.

I have elsewhere (Meehl, 1977) distinguished three kinds of openness that are involved in varying degrees in various psychological concepts and that may all be present in the same theoretical construct, namely, (a) openness arising from the indefinite extensibility of our provisional list of operational indicators of the construct; (b) openness associated with each indicator singly, because of the empirical fact that indicators are only probabilistically, rather than nomologically, linked to the inferred theoretical construct; and (c) openness due to the fact that most of our theoretical entities are introduced by an implicit or contextual definition, that is, by their role in the accepted nomological network, rather than by their inner nature. By their "inner nature" I mean nothing spooky or metaphysical but merely their ontological structure or composition as the latter will, with the progress of research, be formulatable in terms of the theoretical entities of more basic sciences in Comte's pyramid. In social and biological science, one should keep in mind that *explicit definition* of theoretical entities is seldom achieved in terms of the initial observational variables of those sciences, but it becomes possible instead by theoretical reduction or fusion. Explicit definition is achieved, if ever, in terms of some more basic underlying science (Meehl, 1977, see also Cronbach & Meehl (1955/1973); Meehl, 1959/1973f, 1973h, pp. 285–288).

A final remark, which also deserves fuller treatment in another place, is that when we

deal with open concepts, as in personality psychometrics of traits or taxa, the statistical phenomenon of *psychometric drift* as a result of bootstrap operations, refinement of measures, and theoretical reflection on the big matrix of convergent and discriminative validities (Campbell & Fiske, 1959) also generates, via our reliance on implicit or contextual definitions of theoretical entities, an associated *conceptual drift*, a meaning shift. When we reassign weight to fallible indicators of an entity to the extent that the very meaning of the term designating that entity is specified by its role in the network, such reassignment of weights—especially under drastic revisions of the system such as dropping a previously relied-upon indicator—constitutes a change in the theoretical concept. Difficult interpretative and research strategy problems arise here, because, on the one hand (especially in psychometrics) we encounter the danger that the resulting conceptual drift has pulled us away from what we started out to measure, but we also recognize that in psychology, as in the other sciences, part of the research aim is precisely that of bringing about revisions of concepts on the basis of revisions of the nomological network that implicitly defines them. We want, as Plato said, to carve nature at its joints; and the best test of this achievement is increased order in our material.

17. *Intentionality, Purpose, and Meaning*

We do not need to settle the philosopher's question of what is the essential condition for the existence of intentionality, nor buy Brentano's famous criterion that intentionality is the distinctive mark of the mental, to recognize that human beings think and plan and intend, that if rats do so they do it at a much lower level, that sunflowers probably do not, and that stones certainly do not. The formulation of powerful functional relationships for systems that do not possess the capacity to think, worry, regret, plan, and intend is obviously on the average an easier task. (But see Vico, 1744/1948, for a view so different that an American social scientist of our time can hardly grasp it.)

18. *Rule Governance*

Related to intentionality but sufficiently important to deserve a special listing is the fact that human behavior is rule governed. People do something not merely "in accordance with" a generalization but because they feel bound to obey the generalization stated in the form of a rule. Nobody has succeeded in coming up with a fully satisfactory definition of when a rule is a rule, but a sufficiently good approximation is to say that a rule differs from an empirical generalization in that a rule is not liquidated by being broken, whereas an empirical generalization is thereby liquidated (assuming that the conditions stated in its antecedent clause are granted, and the violation event is admitted into the corpus). Continued controversies in psycholinguistics reflect the importance of this kind of consideration in any discussion of human conduct.

19. *Uniquely Human Events and Powers*

In addition to being rule governed, there are several other human features that we do not share with chimpanzees, let alone sponges or boulders. I recall the late Richard M. Elliott saying that the main reason that psychology had done so poorly in its "theories" of humor is that man is the only animal that laughs. I think he had a good point here, since we have learned so much about aspects of human functioning, such as digestion and reproduction, by the experimental study of animals. There are a number of other things that human beings do that no infrahuman animal does, so far as we know. Only man speculates about nonpractical, theoretical matters; only man worships; only man systematically goes about seeking revenge, years later, for an injury done to him; only man carries on discussions about how to make decisions; and there are some features of cultural transmission that only man engages in, although the evidence now indicates that numerous other species transmit learned forms of behavior to subsequent generations.

20. *Ethical Constraints on Research*

This one is so obvious as to need no exposition. One can readily conceive quasi-definitive

experiments on the IQ-heredity controversy, whether there are family dynamics sufficient to make just anyone into a manic-depressive, that cannot be performed because to do so would be immoral.

Not to be overly pessimistic, let me mention (without proof) five noble traditions in clinical psychology that I believe have permanent merit and will still be with us 50 or 100 years from now, despite the usual changes. Some of these are currently unpopular among those addicted to one of the contemporary fly-by-night theories, but that does not bother me. These five noble traditions are (a) descriptive clinical psychiatry, (b) psychometric assessment, (c) behavior genetics, (d) behavior modification (I lump under this rubric positive contingency management, aversion therapy, and desensitization), and (e) psychodynamics. This list should convince you that I am not using methodological arguments to grind any substantive ax. I am probably one of the few psychologists alive today who would list all five of these as great, noble, and enduring intellectual traditions. I particularly emphasize the last, psychodynamics, since I am often perceived as a dust bowl empiricist who does not think that anything can be true or useful if it is not either based on laboratory experiments or statistical correlations. There is not a single experiment reported in my 23-volume set of the standard edition of Freud nor is there a *t* test. But I would take Freud's clinical observations over most people's *t* tests any time. I am confident that psychoanalytic concepts will be around after rubber band theory, transactional theory, attachment theory, labeling theory, dissonance theory, attribution theory, and so on, have subsided into a state of innocuous desuetude like the risky shift and level of aspiration. At the very least, psychoanalysis is an interesting theory, which is more than I can say about some of the "theories" that are currently fashionable.

These five noble traditions differ greatly in the methods they use and their central concepts, and I am hard put to say what is common among them. Some of them, such as behavior modification, are not conceptually exciting to those of us who are interested in ideas like Freud's, but they more than make up for that by their remarkable technological power.

I shall focus the remainder of my remarks on one feature that they have in common with the developed sciences (physical or biological); to wit, they were originally developed with negligible reliance on *statistical significance testing*. Even the psychometric assessment tradition in its early stages paid little attention to significance testing except (sometimes) for finding good items. Binet did not know anything about *t* tests, but he drew graphs of the developmental change of items. I suggest to you that Sir Ronald has befuddled us, mesmerized us, and led us down the primrose path. I believe that the almost universal reliance on merely refuting the null hypothesis as the standard method for corroborating substantive theories in the soft areas is a terrible mistake, is basically unsound, poor scientific strategy, and one of the worst things that ever happened in the history of psychology.

It is easiest to see this from the methodological viewpoint of Sir Karl Popper, but fortunately we have here a rare instance in which Sir Karl's position yields the same result as the Bayesians', and both give the same result as "scientific common sense" practiced by those chemists and biologists who know nothing about philosophy of science or Bayesian statistics and could not care less about either. Briefly and simplistically, the position of Popper and the neo-Popperians is that we do not "induce" scientific theories by some kind of straightforward upward seepage from the clearly observed facts, nor do we "confirm" theories as the Vienna positivists supposed. All we can do is to subject theories—including the wildest and "unsupported" armchair conjectures (for a Popperian, completely kosher)—to grave danger of refutation, in accordance with the formally valid fourth figure of the implicative syllogism: $p \rightarrow q, \sim q, \therefore \sim p$, Popper's famous *modus tollens*.

A theory is corroborated to the extent that we have subjected it to such risky tests; the more dangerous tests it has survived, the better corroborated it is. If I tell you that Meehl's theory of climate predicts that it will rain sometime next April, and this turns out to be the case, you will not be much impressed with my "predictive success." Nor will you be impressed if I predict more rain in April

than in May, even showing three asterisks (for $p < .001$) in my t -test table! If I predict from my theory that it will rain on 7 of the 30 days of April, and it rains on exactly 7, you might perk up your ears a bit, but still you would be inclined to think of this as a "lucky coincidence." But suppose that I specify *which* 7 days in April it will rain and ring the bell; then you will start getting seriously interested in Meehl's meteorological conjectures. Finally, if I tell you that on April 4th it will rain 1.7 inches (.66 cm), and on April 9th, 2.3 inches (.90 cm) and so forth, and get seven of these correct within reasonable tolerance, you will begin to think that Meehl's theory must have a lot going for it. You may believe that Meehl's theory of the weather, like all theories, is, when taken literally, false, since probably all theories are false in the eyes of God, but you will at least say, to use Popper's language, that it is beginning to look as if Meehl's theory has considerable *verisimilitude*, that is, "truth-likeness." (An adequate reconstruction of the verisimilitude concept has yet to be provided by our logician friends, see, e.g., Popper, 1976, but few reflective psychologists will doubt that some such notion of "nearness to the truth" is unavoidable when we evaluate theories. It is crucial to recognize that verisimilitude is an ontological, not an epistemological, concept that must not be conflated with confirmation, probability, evidence, proof, corroboration, belief, support, or plausibility.)

Popperians would speak of low logical or prior probability, of the high content (forbidding much), because it specifies exactly which days it will rain how many inches. A Bayesian (who would reject Popper's philosophy on the grounds that we want our "theoretical prior" to be *high* to get a nice boost out of Bayes' theorem when the facts turn out right) would express Popper's point by saying that we want what Pap (1962, p. 160) calls the *expectedness*, the prior on the observations that is found in the denominator of Bayes' theorem to be low. An unphilosophical chemist or astronomer or molecular biologist would say that this was just good sensible scientific practice, that a theory that makes precise predictions and correctly picks out *narrow intervals* or *point values* out of the range

of experimental possibilities is a pretty strong theory. There are revisions (as I think, necessary) of the classic Popperian position urged on us by his heretical exstudents P. K. Feyerabend and the late Imre Lakatos, but psychologists must reach at least the stage of Bayes and Popper before they can profitably go on to the refinements and criticisms of these gentlemen.

The most important caveat I would adjoin to Sir Karl's falsifiability requirement arises from the considerations pressed by Feyerabend (1962, 1965, 1970, 1971), Lakatos (1970, 1974a, 1974b), and others concerning the crucial role of auxiliary theories in subjecting the main substantive theory of interest to danger of *modus tollens*. As is well-known (and not disputed by Popper), when we spell out in detail the logical structure of what purports to be an observational test of a theoretical conjecture T , we normally find that we cannot get to an observational statement from T alone. We require further a set of often complex and problematic auxiliaries A , plus the empirical realization of certain conditions describing the experimental particulars, commonly labeled collectively as C . So that the derivation of an observation from a substantive theory T amounts always to the longer formula $(T.A.C) \rightarrow O$, rather than the simplified schema $(T \rightarrow O)$ that most of us learned in undergraduate logic courses. This presents a problem not perhaps for Popper's main thesis (although some critics do say this) but for its application as a criterion of the scientific status of theories (or the scientific approach of a particular theoretician or investigator?). The *modus tollens* now reads: Since $(T.A.C) \rightarrow O$, and we have falsified O observationally, we have the consequence $\sim(T.A.C)$. Unfortunately, this result does not entail the falsity of T , the substantive theory of interest but only the falsity of the conjunction $(T.A.C)$; that is, we have proved a disjunction of the falsities of the conjuncts. So the failure to get the expected observation O proves that $\sim T \vee \sim A \vee \sim C$, which is not quite what we would like to show.

One need not subscribe to the famous Duhemian thesis regarding falsification of science as a whole (Grünbaum, 1960, 1962, 1969, 1976) or to the Lakatosian exposition (La-

katos, 1970, 1974a, 1974b) about the protective belt of auxiliaries against which the *modus tollens* is directed versus the hard core of the theory against which the *modus tollens* is, prior to a Kuhnian revolution (Kuhn, 1970a, 1970b, 1970c), forbidden to be directed, to see that there is a difficult problem presented to even a neo-Popperian (like myself), because in social science the auxiliaries *A* and the initial and boundary conditions of the system *C* are frequently as problematic as the theory *T* itself. *Example*: Suppose that a personologist or social psychologist wants to investigate the effect of social fear on visual perception. He attempts to mobilize anxiety in a sample of adolescent males, chosen by their scores on the Social Introversion (*Si*) scale of the Minnesota Multiphasic Personality Inventory (MMPI), by employing a research assistant who is a raving beauty, instructing her to wear Chanel No. 5, and adopt a mixed seductive and castrative manner toward the subjects. An interpretation of a negative empirical result leaves us wondering whether the main substantive theory of interest concerning social fear and visual perception has been falsified, or whether only the auxiliary theories that the *Si* scale is valid for social introversion and that attractive but hostile female experimenters elicit social fear in introverted young males have been falsified. Or perhaps even the particular conditions were not met; that is, she did not consistently act the way she was instructed to or the MMPI protocols were mis-scored.

There is nothing qualitatively unique about this problem for the inexact sciences, but it is quantitatively more severe for us than for the chemist or astronomer, for at least two reasons, which I shall set forth without either proving or developing them here. First, independent testing of the auxiliary theories (which often means validation of psychometric instruments or ascertaining efficacy of social stimulus inputs) is harder to carry out. Due to unavoidable looseness of the nomological network (Cronbach & Meehl, 1955/1973) plus the factors in the list of 20 difficulties *supra*, the range of research circumstances in which auxiliaries *A* are problematic is greater than in the exact sciences or in some but not all of the biological sciences. Second,

a point to which philosophers of science have devoted little attention, in physics or chemistry there is usually a more intimate connection, sometimes one of contributing to derivability, between the substantive theory of interest T and components of the auxiliaries A . This is sometimes even true in advanced branches of biology. *Example*: There is a complicated, well-developed, and highly corroborated theory of how a cyclotron works, and the subject matter of that auxiliary "theory of the instrument" is for the most part identical to the subject matter of the physical theories concerning nuclear particles, and so on, being investigated by the physicist. Devices for bringing about a state of affairs, for isolating the system under study, and for observing what occurs as a result are all themselves legitimated by theory.

It seems there is a sense in which auxiliary theories used by physical and biological scientists are at least subtly informed by what may be loosely called *the spirit*, the leading ideas, the core, and pervasive concepts of the main substantive theory *T*, although not rigorously derivable from *T*. When this is not so, scientists are likely to consider the (*T.A.*) system as "unaesthetic," "incoherent," even *ad hoc*. These fascinating matters remain to be analyzed and reconstructed by logicians, but most scientists and historians of science are—however informally—well aware of their influence. (See, e.g., Holton, 1973.)

In the social sciences, no such intimate connection, and almost never a relation of theoretical derivability, exists; hence, the auxiliary theory (such as a theory that the Rorschach is valid for detecting subclinical schizoid cognitive slippage or that Chanel-doused beauteous research assistants are anxiety elicitors) must stand on its own feet. Almost nothing we know or conjecture about the substantive theory helps us to any appreciable degree in firming up our reliance on the auxiliary. The situation in which *A* is merely conjoined to *T* in setting up our test of *T* makes it hard for us social scientists to fulfill a Popperian falsifiability requirement—to state before the fact what would count as a strong falsifier.

I shall illustrate this problem further with a simple example whose adequate exposition

will appear elsewhere (Golden & Meehl, in press). Suppose that I wish to test my dominant gene conjecture (Golden & Meehl, 1978; Meehl, 1972, 1972/1973g, 1977) concerning *schizotaxia* as the central nervous system condition for the development by social learning of *schizotypy* (Meehl, 1962/1973c), which in turn is the personality precondition for the development of a *clinical schizophrenia*—although the latter must then occur only in one fourth of the persons carrying the gene, given the roughly 12% concordance for first-degree relatives as regards diagnosable clinical schizophrenia. (See also Böök, 1960; Heston, 1966, 1970; Slater, 1958/1971). I might rely on some complex neurological or projective or structured test “sign” as having such-and-such estimated construct validity for the schizotypal personality makeup. Such a quantitative estimate might be made relying on a combination of empirical evidence concerning discordant monozygotic twins of known schizophrenics, protocols of persons tested as college freshmen who subsequently decompensate into a recognizable schizophrenia, and the like. Such numerical estimates will all suffer not only from the usual test unreliability and random sampling fluctuations, but they will also have some unknown degree of systematic bias. For instance, it clearly will not do to assume that the taxon *all compensated schizotypes* would average the same scores on a Rorschach or MMPI indicator variable as do the compensated (discordant) monozygotic twins, the latter being a biased selection, since they have the same potentiating genes that their decompensated twins have. However, there must be something else about them—of an environmental sort—that works strongly in their favor and helps keep them discordant, that is, clinically well. One simply has no way of ascertaining the net impact of these two opposed kinds of forces on the psychometric results.

Suppose that we take some combination of earlier findings on preschizophrenics, remitted schizophrenics, compensated discordant monozygotic twins of schizophrenics, and so forth, and we ascertain that while the valid positive rate p_a among these safely presumed schizotypes varies (even if the sample sizes are huge, it will always vary in an amount unexplainable

by random sampling fluctuation), it nevertheless shows a “reasonably close” agreement. (Again, we think like physicists or physiologists instead of like social scientists fooling around with t tests.) So we strike some kind of rough average \bar{p}_a of these several valid positive rates, knowing that it is the best we can do at this point with data on different groups of schizotypes, who, despite their differences, must all have somehow been tagged as such. Given that estimated valid positive rate, and given a false positive rate p_n (also systematically biased because of the undiagnosed compensated schizotypes in any “control population”), we record our numerical predictions for the incidence of our psychometric sign among parent pairs of schizophrenic probands (where, on the dominant gene theory, we expect not only a 50% schizotypy incidence but something stronger; to wit, at least one member of each parent pair must be a schizotype). We also compute it for siblings and dizygotic twins and—although here things get a bit feeble—with sufficiently large samples, maybe second-degree relatives. Thus, for instance, the expected sign-positive rate among parents (and sibs, if they all cooperate) is given by the simple expression $p^* = \frac{1}{2}p_a + \frac{1}{2}p_n$.

Now the substantive dominant gene theory T , when conjoined with the auxiliary theory A concerning psychometric validity, and assuming that we have identified the right relatives and the probands were all schizophrenics [=C], generates point predictions and therefore takes a high Popperian risk *when the conjunction (T.A.C) is considered as the “theory” under test*. Hence, the verification of those numerical point predictions as to the values of the psychometric incidence in relatives of different degrees of consanguinity provides a strong Popperian test for that conjunctive “theory.” One would then normally say that successful negotiation of this hurdle, the failure to be clobbered *modus tollens* by the outcome of the empirical study, provides a moderate to strong corroboration of the conjunctive theory. Hence, (T.A.C) is doing well; that is, it has escaped falsification despite taking a high risk by making several numerical point predictions.

So far, so good, and Popper as well as his critics would have no complaint. However, the

classical Popperian requirement on playing the scientific game fairly involves the theoretician's saying, before doing the research, what would count as a strong basis for rejecting the theory. If "the theory" is taken to be the substantive theory *T* (which it is, if one is not being philosophically disingenuous) rather than the psychometric auxiliary and diagnostic validity conjectures *A* and *C*, then one will be committing what amounts in spirit to a Popperian sin against falsificationism as a method. If the empirical research does not pan out as predicted, one does not abandon *T*; instead he tells us that either *T* is incorrect, *A* is incorrect, or the diagnoses were untrustworthy!

I am not persuaded from his writings nor from conversations that I have had with him that Sir Karl adequately appreciates the degree to which this theory and auxiliary problem permeate research in the inexact sciences, especially the social sciences in their soft areas. Whether it presents a general problem for the Popperian formulation of scientific method is beyond the scope of this article and my competence. It is perhaps worth saying, however, for the benefit of philosophically oriented readers, that the above described situation—certainly no rarity in our field or in biology—may represent a social fact about the way science works that presents grave difficulties for the Popperian reconstruction. That is, the stipulation beforehand that one will be pleased about substantive theory *T* when the numerical results come out as forecast, but will not necessarily abandon it when they do not, seems on the face of it to be about as blatant a violation of the Popperian commandment as you could commit. For the investigator, in a way, is doing what Popper says we ought not to do, and what astrologers and Marxists and psychoanalysts allegedly do, playing "heads I win, tails you lose." But it seems in accordance with much scientific practice and, as far as I have sampled, with most persons' scientific common sense or intuitions, to say that if the combination (*T.A.C*) generates a high-risk numerical point prediction, such a result really does support all three of the components. The reason it does so seems pretty clear, despite its commonsense, non-formalized character: Because of the lack of intimate inner connection in the inexact sci-

ences between the components of these conjunctions, it would strike us as a *very strange coincidence* if the substantive theory *T* should have low verisimilitude (which would, were *T* true, also generate mispredictions of the numerical point values) and yet the two (largely unrelated) "wrongs" of *T* and *A* are somehow systematically balanced so as to generate the same numerical prediction generated from the conjecture that *T* and *A* both have relatively high verisimilitude.

Such a delicate quantitative counterbalancing of theoretical errors is not impossible, but it seems quite implausible, assuming that nature is (as Einstein says) "subtle but not malicious." So I think we are not being unreasonable to congratulate ourselves on arriving at a successful prediction of high-risk point values or other antecedently improbable observational patterns from the conjunction (*T.A.C*), despite the fact that we seem to be hedging when we say before the fact that we will not consider our substantive theory *T* falsified by a bad result if it does not pan out. These are problems that need further exploration by statisticians and philosophers of science, especially in light of work on the history of science, and with special attention to the question of whether there are important differences between the inexact and the exact sciences, or even between the biological and social sciences, as to how a Popperian or neo-Popperian methodology should be explained and applied.

But, you may say, what has all this got to do with significance testing? Isn't the social scientist's use of the null hypothesis simply the application of Popperian (or Bayesian) thinking in contexts in which probability plays such a big role? No, it is not. One reason it is not is that the usual use of null hypothesis testing in soft psychology as a means of "corroborating" substantive theories does not subject the theory to grave risk of refutation *modus tollens*, but only to a rather feeble danger. The kinds of theories and the kinds of theoretical risks to which we put them in soft psychology when we use significance testing as our method are *not* like testing Meehl's theory of weather by seeing how well it forecasts the number of inches it will rain on certain days. Instead, they are depressingly close

to testing the theory by seeing whether it rains in April at all, or rains several days in April, or rains in April more than in May. It happens mainly because, as I believe is generally recognized by statisticians today and by thoughtful social scientists, the null hypothesis, taken literally, is always false. I shall not attempt to document this here, because among sophisticated persons it is taken for granted. (See Morrison & Henkel, 1970, especially the chapters by Bakan, Hogben, Lykken, Meehl, and Rozeboom.) A little reflection shows us why it has to be the case, since an output variable such as adult IQ, or academic achievement, or effectiveness at communication, or whatever, will always, in the social sciences, be a function of a sizable but finite number of factors. (The smallest contributions may be considered as essentially a random variance term.) In order for two groups (males and females, or whites and blacks, or manic depressives and schizophrenics, or Republicans and Democrats) to be *exactly* equal on such an output variable, we have to imagine that they are exactly equal *or* delicately counterbalanced on all of the contributors in the causal equation, which will never be the case.

Following the general line of reasoning (presented by myself and several others over the last decade), from the fact that the null hypothesis is always false in soft psychology, it follows that the probability of refuting it depends wholly on the sensitivity of the experiment—its logical design, the net (attenuated) construct validity of the measures, and, most importantly, the sample size, which determines where we are on the statistical power function. Putting it crudely, if you have enough cases and your measures are not totally unreliable, the null hypothesis will always be falsified, *regardless of the truth of the substantive theory*. Of course, it could be falsified in the wrong direction, which means that as the power improves, the probability of a corroborative result approaches one-half. However, if the theory has no verisimilitude—such that we can imagine, so to speak, picking our empirical results randomly out of a directional hat apart from any theory—the probability of refuting by getting a significant difference in the wrong direction also approaches one-half. Obviously, this is quite un-

like the situation desired from either a Bayesian, a Popperian, or a commonsense scientific standpoint. As I have pointed out elsewhere (Meehl, 1967/1970b; but see criticism by Oakes, 1975; Keuth, 1973; and rebuttal by Swoyer & Monson, 1975), an improvement in instrumentation or other sources of experimental accuracy tends, in physics or astronomy or chemistry or genetics, to subject the theory to a greater risk of refutation *modus tollens*, whereas improved precision in null hypothesis testing usually decreases this risk. A successful significance test of a substantive theory in soft psychology provides a feeble corroboration of the theory because the procedure has subjected the theory to a feeble risk.

But, you may say, we do not look at just one; we look at a batch of them. Yes, we do; and how do we usually do it? In the typical *Psychological Bulletin* article reviewing research on some theory, we see a table showing with asterisks (hence, my title) whether this or that experimenter found a difference in the expected direction at the .05 (one asterisk), .01 (two asterisks!), or .001 (three asterisks!!) levels of significance. Typically, of course, some of them come out favorable and some of them come out unfavorable. What does the reviewer usually do? He goes through what is from the standpoint of the logician an almost meaningless exercise; to wit, he *counts noses*. If, say, Fisbee's theory of the mind has a batting average of 7:3 on 10 significance tests in the table, he concludes that Fisbee's theory seems to be rather well supported, "although further research is needed to explain the discrepancies." This is scientifically a preposterous way to reason. It completely neglects the crucial asymmetry between confirmation, which involves an inference in the formally invalid third figure of the implicative syllogism (this is why inductive inferences are ampliative and dangerous and why we can be objectively wrong even though we proceed correctly), and refutation, which is in the valid fourth figure, and which gives the *modus tollens* its privileged position in inductive inference. Thus the adverse tests, seen properly, do Fisbee's theory far more damage than the favorable ones do it good.

I am not making some nit-picking statistician's correction. I am saying that the whole business is so radically defective as to be scientifically almost pointless. This is not a technical hassle about whether Fisbee should have used the varimax rotation, or how he estimated the communalities, or that perhaps some of the higher order interactions that are marginally significant should have been lumped together as a part of the error term, or that the covariance matrices were not quite homogeneous. I am not a statistician, and I am not making a statistical complaint. I am making a philosophical complaint or, if you prefer, a complaint in the domain of scientific method. I suggest that when a reviewer tries to "make theoretical sense" out of such a table of favorable and adverse significance test results, what the reviewer is actually engaged in, willy-nilly or unwittingly, is meaningless substantive constructions on the properties of the statistical power function, and almost nothing else.

This feckless activity is made worse by the almost universal practice of what I call *step-wise low validation*. By this I mean that we rely on one investigation to "validate" a particular instrument and some other study to validate another instrument, and then we correlate the two instruments and claim to have validated the substantive theory. I do not argue that this is a scientific nothing, but it is about as close to a nothing as you can get without intending to. Consider that I first show that Meehl's Mental Measure has a validity coefficient (against the criterion I shall here for simplicity take to be quasi-infallible or definitive) of, say, .40—somewhat higher than we usually get in personology and social psychology! Then I show that Glotz's Global Gauge has a validity for its alleged variable of the same amount. Relying on these results, having stated the coefficient and gleefully recorded the asterisks showing that these coefficients are not zero (!), I now try to corroborate the Glotz-Meehl theory of personality by showing that the two instruments, each having been duly "validated," correlate .40, providing, happily, some more asterisks in the table. Now just what kind of a business is this? Let us suppose that each instrument has a reliability of .90 to make it easy. That means that

the portion of construct-valid variance for each of the devices is around one fifth of the reliable variance and the same for their overlap when correlated with each other. I do not want to push the discredited (although recently revived) principle of indifference, but without other knowledge, it is easily possible, and one could perhaps say rather likely, that the correlation between the two occurs in a region of each one's components that has literally nothing to do with either of the two criterion variables used in the validity studies relied on. This is, of course, especially dangerous in light of the research that we have on the contribution of methods variance.

I seem to have trouble conveying to my students and colleagues just how dreadful a mess of flabby inferences this kind of thing involves. It is as if we were interested in the effect of sunlight on the mating behavior of birds, but not being able to get directly at either of these two things, we settle for correlating a proxy variable like field-mice density (because the birds tend to destroy the field mice) with, say, incidence of human skin cancer (since you can get that by spending too much time in the sun!) You may think this analogy dreadfully unfair; but I think it is a good one. Of course, the whole idea of simply counting noses is wrong, because a theory that has seven facts for it and three facts against it is *not* in good shape, and it would not be considered so in any developed science.

You may say, "But, Meehl, R. A. Fisher was a genius, and we all know how valuable his stuff has been in agronomy. Why shouldn't it work for soft psychology?" Well, I am not intimidated by Fisher's genius, because my complaint is not in the field of mathematical statistics; and as regards inductive logic and philosophy of science, it is well-known that Sir Ronald permitted himself a great deal of dogmatism. I remember my amazement when the late Rudolf Carnap said to me, the first time I met him, "But, of course, on this subject Fisher is just mistaken; surely you must know that." My statistician friends tell me that it is not clear just how useful the significance test has been in biological science either, but I set that aside as beyond my competence to discuss. The shortest answer to this rebuttal about agronomy, and one that has general im-

portance in thinking about soft psychology, is that we must carefully distinguish *substantive theory* from *statistical hypothesis*. There is a tendency in the social sciences to conflate these in talking about our inferences. (A neglected article by Bolles, 1962, did not cure the psychologists' disease.) The substantive theory is the theory about the causal structure of the world, the entities and processes underlying the phenomena; the statistical hypothesis is a much more restricted and "operational" conjecture about the value of some parameter, such as the mean of a specified statistical population. The main point in agronomy is that the logical distance, the difference in meaning or content, so to say, between the alternative hypothesis and substantive theory *T* is so small that only a logician would be concerned to distinguish them. *Example*: I want to find out whether I should be putting potash on the ground to help me raise more corn. Now everybody knows from common sense as well as biology that the corn gets its nutrients from the soil, and furthermore that the yield of corn at harvest time is not causally efficacious in determining what I did in the spring, random numbers aside. If I refute the statistical null hypothesis that plots of corn with potash do not differ in yield from plots without potash, I have thereby proved the alternative hypothesis—that there *is* a difference between these two sorts of plots; and the only substantive conclusion to draw, given such a difference, is that the potash made the difference. Such a situation, in which the content of the substantive theory is logically quasi-identical with the alternative hypothesis, which was refuted by our significance test, is completely different from the situation in soft psychology. Fisbee's substantive theory of the mind is not equivalent, or anywhere near equivalent, to the alternative hypothesis. All sorts of competing theories are around, including my grandmother's common sense, to explain the nonnull statistical difference. So the psychologist can take little reassurance about the use of significance tests from knowing that Fisher's approach has been useful in studying the effect of fertilizer on crop yields.

Although this presents a pretty depressing picture, I daresay that the Skinner disciples among you will be inclined to think,

well, that's just one more way of showing what we have known all along. The point is to prove that you have achieved experimental control over your subject matter, as Skinner says. If you have, I am not much interested in tabular asterisks; if you haven't, I'm not interested in them either.

But that is easy for Skinnerians because their theory (it is a theory in Sir Karl Popper's sense) is close to a pure dispositional theory, and does not usually present us with the kind of evidentiary evaluation problem that we get with entity-postulating theories such as those of Freud, Hull, Albert Ellis, or, to come closer to home, my conjectures about schizophrenia or hedonic deficit (Meehl, 1972, 1974, 1975, 1962/1973c, 1972/1973g). Those of us whose cognitive passions are incompletely satisfied by dispositional theories, whether Skinnerian or psychometric, should ask ourselves what *kind* of inferred entity construction we want and how it could generate the sorts of intellectual "surprises" that Robert Nozick (1974, pp. 18–22) considers typical of invisible hand theories, which have proved so eminently successful in the physical and biological sciences and—somewhat less so—in economics. Some directions of solution (before I go on to the one that I am using in my own research) follow.

We could take the complex form of Bayes's theorem more seriously in concrete application to various substantive theories to take into account, even if crudely in the sense of setting upper and lower bounds to the probabilities involved, the logical asymmetry between confirmation and refutation (see, e.g., Maxwell, 1974). Second, it may be that the Fisherian tradition, with its soothing illusion of quantitative rigor, has inhibited our search for stronger tests, so we have thrown in the sponge and abandoned hope of concocting substantive theories that will generate stronger consequences than merely "the Xs differ from the Ys." Thus, for instance, even when we cannot generate numerical point predictions, (the ideal case found in the exact sciences), it may be that we can at least predict the order of numerical values or the rank order of the first-order numerical differences, and the like.

Sometimes in the other sciences it has been possible to concoct a middling weak theory that, while incapable of generating numerical

point values, entails a certain *function form*, such as a graph should be an ogive or that it should have three peaks and that these peaks should be increasingly high, and that the distance on the abscissa between the first two peaks should be less than the distance between the second two. In the early history of quantum theory, physicists relied on Wien's law, which related "some (unknown) function" of wavelength to energy multiplied by the fifth power of wavelength. In the cavity radiation experiment, the empirical points were simply plotted at varying temperatures, and it was evident by inspection that they fell on the same curve, even though a formal expression for that curve was beyond the theory's capabilities (Eisberg, 1961, pp. 50-51).

Talking of Wien's law is a good time for me to recommend to psychologists who disagree with my position to have a look at any textbook of theoretical chemistry or physics, where one searches in vain for a statistical significance test (and finds few confidence intervals). The power of the physicist does not come from exact assessment of probabilities that a difference exists (which physicists would view as a ludicrous thing to show), nor by the verbal precision of so-called "operational definitions" in the embedding text. The physicist's scientific power comes from two other sources, namely, the immense deductive fertility of the formalism and the accuracy of the measuring instruments. The scientific trick lies in conjoining rich mathematics and experimental precision, a sort of "invisible hand wielding fine calipers." The embedding text is sometimes surprisingly loose, free-wheeling, even metaphorical—as viewers of television's *Nova* are aware, seeing Nobel laureates discourse whimsically about the charm, strangeness, and gluons of nuclear particles (see, e.g., Nambu, 1976). One gets the impression that when you have a good science going, with potent mathematics and accurate instruments, you can be relaxed and easygoing about the words. Nothing is as stuffy and pretentious as the verbal "pseudorigor" of the soft branches of social science. In my modern physics text, I am unable to find one single test of statistical significance. What happens instead is that the physicist has a sufficiently powerful invisible hand theory that enables him to generate an

expected curve for his experimental results. He plots the observed points, looks at the agreement, and comments that "the results are in reasonably good accord with theory." Moral: *It is always more valuable to show approximate agreement of observations with a theoretically predicted numerical point value, rank order, or function form, than it is to compute a "precise probability" that something merely differs from something else.* Of course, we do not have precise probabilities when we do significance testing because of the falsity of the assumptions generating the table's values and varying robustness of our tests under departures from these assumptions.

The only possible "solution" to the theory-refutation problem that I have time to discuss in any detail is what I call *consistency tests* (Meehl, Note 3). Unfortunately, this approach is not easily available for most theoretical problems in soft psychology, although I am not prepared to say that it is confined to the domain in which I have been developing it, namely, taxometrics, that is, the application of psychometric procedures to depiction of a taxonic situation and classification of individuals into the taxon or outside of it. From our conjectures about the latent causal situation, we derive formulas for estimating the theoretical quantities of interest, such as the proportion of schizotypes in a given clinical population, the mean values of the schizotypal and nonschizotypal classes, the optimal cut ("hitmax") on each phenotypic indicator variable for classifying individuals, and the proportion of valid and false positives achieved by that cut. But we realize that our conjectures about the latent situation may be false or that the indicators relied on may have too low validity, or that they may be more correlated within the taxa than desired, and so forth. Second, even if the basic formal structure postulated is approximated by the state of nature (e.g., there is a schizoid taxon, the indicators have sizable validity, the intra-taxon distributions are quasi-normal or at least unimodal, the correlation of the indicators within the groups is small, and the departures from these various hypotheses are within the tolerance allowed by the method's robustness), it may still be that we have suffered some kind of systematic bias on one of

the indicators due to a nuisance variable such as social class, or that we have had bad luck in the sample, so the method's numerical deliverances on this occasion are untrustworthy.

Whether the abstract causal structure postulated is unsound or the numerical values found in this sample are seriously in error, we need some method of checking the data internally to find out whether these unfortunate possibilities have materialized. We do this by deriving theorems within the formalism specifying how various numerical values (observed or calculated from the observed) should be related to each other, so that when they are not related as the consistency theorem demands, we are alerted to the danger that something is rotten in the state of Denmark (see Meehl, 1973d). Unfortunately, most of the work, both mathematical and empirical, is as yet only available in mimeographed reports from our laboratory (Golden, 1976; Golden & Meehl, Note 1, Note 2; Meehl, Note 3, Note 4). What survives scrutiny will be found in a book in preparation with my former student and research colleague Robert Golden (Golden & Meehl, in press).

One taxometric procedure, which I have christened *maxcov-hitmax* (Meehl, 1973d) relies on the following theorem: If three fallible indicator variables are negligibly correlated within a diagnostic taxon and within the extra taxon population, then the covariance of any pair of these is maximized in that class interval on the third indicator that contains the hitmax (optimal, fewest misses) cut on the third indicator. That is, $\text{cov}(yz)$ has its largest value for the subset of patients falling in the hitmax interval on x . Starting from this relation we go through a sequence of calculations yielding estimates of the base rate P of the taxon, the frequency distributions of all three of the fallible indicators, the location of all three hitmax cuts, and the inverse probability of taxon membership (via Bayes' theorem) for a patient who has any given combination of the three signs plus or minus.

Our Monte Carlo runs and our single application to a real case in which we know the true answer and pretend not to know it, namely, biological sex diagnosed by three MMPI femininity keys, have been most encouraging and suggest that the method is

powerful and quite robust under departures from the simplifying hypotheses. But applying it to a situation in which we do not know the true answer (such as "What is the proportion of unrecognized schizotypes in a mixed psychiatric population?"), how much faith should we have in our numerical results? The best way I know to go about this, since mere replication of the inferred parameter estimates does not answer the question, is by the use of consistency tests. For example, one of the consistency tests in this kind of two-category taxonic situation is this: If we form the product of the differences between the inferred latent means on y and z (schizotypes minus non-schizotypes) and then multiply this product $\Delta\bar{y}\Delta\bar{z}$ by the product of the inferred schizotypal base-rate P and its complement Q , then it can be shown that this theoretically calculated quantity should equal the grand covariance of y and z computed directly from the observations. We call this the "total covariance consistency test."

Of course, such a relation is not required to be literally true, because it is known in advance that (a) the impoverished theory has imperfect verisimilitude and (b) all statistical estimates are subject to both systematic and random error. (We are *not* going to do a significance test!) What we have is a problem of robustness and detection of excessive departures from the postulated latent conditions. Golden and I arbitrarily said that we would consider a particular sample as delivering sufficiently accurate information if the estimates of base rate and hit rate were within .10 of the true values, and estimated latent means and standard deviations within one class interval of the truth. (Actually we did much better than that on the average. For example, with sample sizes greater than 400, equal variances, two sigma differences of latent means, and zero intrataxon correlations, the average error for P was only .01 and for latent means and sigmas, less than one fourth standard deviation which is one-half the smallest integral class interval.) But if these tolerances strike you as excessively large, I remind you how much more powerful such numerical claims are in soft psychology than the usual flabby "the boys are taller than the girls" or "the schizophrenics are shyer than the manic

6.4		400	.8	8	12	2	2	2	1	.5/.125	0

Note. N = sample size; P = base rate of the taxon; M_o = mean of the extra taxon class on each indicator; M_t = mean of the taxon on each indicator; SD_o = standard deviation of the extra taxon class on each indicator; SD_t = standard deviation of the taxon on each indicator; $D' = (M_t - M_o)/S$, where $S = SD_o + SD_t/2$; r = latent correlation between indicator pairs; F = number of failures of consistency tests in 25 samples.

^a 94% correct.

^b Parameter estimates are always or nearly always accurate.

depressives." We then imposed tolerances on each of the four most promising consistency tests derived within the formalism. For example, if the total covariance consistency test $T_1 = \text{cov}(yz) - PQ (\bar{y}_s - \bar{y}_n) (\bar{z}_s - \bar{z}_n)$ yields a discrepancy greater than $.64 + .74s^2$, a "robustness cut" chosen by a combination of analytical derivation with preliminary Monte Carlo trials, then this particular sample is considered "numerically inconsistent" with Consistency Test T_1 . Now if any one of the four consistency tests is, so to speak, rejected by a given sample, this is a red flag warning

us that we ought not to have much faith in the parametric estimates of interest.

The important question then is, how sensitive are the consistency tests to sample departures from the parametric truth in excess of the tolerance allowed? How often will we draw a sample in which the inferred parameters are in error by more than the tolerance limit imposed but all four consistency tests are satisfied within their tolerance limits, leading us mistakenly to trust our results? Second, how often is at least one of the four consistency tests numerically inconsistent (i.e.,

Table 2
Consistency Test Result

Actual situation	Sample		Total
	Trust-worthy	Suspicious	
Accurate	336	36	372
Inaccurate	0	228	228
Total	336	264	600

outside its tolerance limit) leading us to *mis-trust* the sample when in fact all of the sample estimates of the parameters are within their tolerances? The first of these we might call a "false negative" failure on the part of the consistency tests to function jointly; the second is then a false positive.

I restrict my data presentation to Monte Carlo runs in which the samples are generated from a multivariate normal model, although I want to emphasize that our methods are not generally confined to the normal case. Normality was imposed because of Monte Carlo generating problems. In Table 1, the numbers "Set 1.1, 1.2, . . ." in the first column merely name conditions of fixed population properties and sample sizes, and 25 Monte Carlo samples were drawn per set. The column heads indicate the various population properties, such as taxon base-rate P , the two latent taxon means and standard deviations, the mean difference in standard deviation units, the ratio of latent standard deviations, and the within-group correlations. The important result (F) indicates how many of the 25 samples under the given set conditions were failures of the consistency tests. Thus, the four consistency tests were applied to each sample, which was classified as probably trustworthy (or probably not) in accordance with the tolerance rules for consistency tests. Then the sample was classified as to whether it was *in fact* trustworthy, that is, whether the main latent parameters were all estimated within their allowed tolerance.

Despite the high average accuracy of our taxometric method when evaluated as mean percent errors in estimating each of the latent parameters (base rate, hit rates, means, standard deviations), if a naive trusting taxometrist relied blindly on the method, hoping to

be accurate on all seven parameters on any sample drawn, he would be misled distressingly often were he to lack consistency tests. Among our 600 Monte Carlo samples, all seven latent parameters of the artificial population were estimated to an accuracy within the tolerance levels in 372 samples; that is, on 228 samples at least one parameter was inaccurate. This shows that a trustworthy device for detecting such bad samples is much to be desired. It will not do a taxonomic scientist much good to be "usually quite accurate" if the procedure relied on is nevertheless often (38% of the time) somewhat inaccurate *and the investigator is without a method that warns him when the untoward event has, on a given occasion, occurred.*

In Table 2 the 600 Monte Carlo samples are tallied with respect to each sample's parameter estimation accuracy and whether it passed all four consistency tests. It is encouraging that overall the consistency tests were 94% accurate. Furthermore, the 6% of the samples in which the consistency tests erred were all samples in which they erred conservatively; that is, one or more of the consistency tests was suspiciously outside its tolerance limits, yet none of the latent parameters estimated by the methods was outside *its* tolerance limits. We have not as yet drawn a single Monte Carlo sample (among 600) in which the four consistency tests were conjunctively reassuring but the sample was in fact misleading. This finding suggests that we were unduly stringent, so that if some small amount of leeway were permitted for errors of the other kind, the consistency tests could be somewhat relaxed and, perhaps concurrently, the tolerance limits on the parameter estimates could be somewhat tightened.

There is some interchangeability between original estimators and consistency tests, and the maxcov-hitmax method itself was originally derived by me as a consistency test before I realized that it could better be used as an original search device (see Meehl, Note 3, pp. 28-29; Note 4, pp. 2-6).

Not in reliance on these results, which I present merely as exemplars of a general methodological thesis, I want now to state as strongly as I can a prescription that we should adopt in soft psychology to help get away

from the feeble practice of significance testing: *Wherever possible, two or more non-redundant estimates of the same theoretical quantity should be made, because multiple approximations to a theoretical number are always more valuable, provided that methods of setting permissible tolerances exist, than a so-called exact test of significance, or even an exact setting of confidence intervals.* This is a special case of what my philosopher colleague Herbert Feigl refers to as "triangulation in logical space." It is, as you know, standard procedure in the developed sciences. We have, for instance, something like a dozen independent ways of estimating Avogadro's number, and since they all come out "reasonably close" (again, I have never seen a physicist do a t test on such a thing!), we are confident that we know how many molecules there are in a mole of chlorine.

This last point may lead you to ask, "If consistency tests are as important as Meehl makes them out to be, why we don't hear about them in chemistry and physics?" I have a perfect answer to that query. It goes like this: *Consistency tests are so much a part of standard scientific method in the developed disciplines, taken so much for granted by everybody who researches in chemistry or physics or astronomy or molecular biology or genetics, that these scientists do not even bother having a special name for them!* It shows the sad state of soft psychology when a fellow like me has to cook up a special meta-theory expression to call attention to something that in respectable science is taken as a matter of course.

Having presented what seems to me some encouraging data, I must nevertheless close with a melancholy reflection. The possibility of deriving consistency tests in the taxonic situation rests on the substantive problems presented by fields like medicine and behavior genetics, and it is not obvious how we would go about doing this in soft areas that are non-taxonic. It may be that the nature of the subject matter in most of personology and social psychology is inherently incapable of permitting theories with sufficient conceptual power (especially mathematical development) to yield the kinds of strong refuters expected by Popperians, Bayesians, and unphilosophical

scientists in developed fields like chemistry. This might mean that we could most profitably confine ourselves to low-order inductions, a (to me, depressing) conjecture that is somewhat corroborated by the fact that the two most powerful forms of clinical psychology are atheoretical psychometrics of prediction on the one hand and behavior modification on the other. Neither of these approaches has the kind of conceptual richness that attracts the theory-oriented mind, but I think we ought to acknowledge the possibility that there is never going to be a really impressive theory in personality or social psychology. I dislike to think that, but it might just be true.

Addendum

My colleague, Thomas J. Bouchard, Jr., on reading a draft of this article faulted me for what he saw as a major inconsistency between my neo-Popperian emphasis on falsifiability and my positive assessment of Freud. There is no denying that for such a quantitatively oriented product of the "dust-bowl empiricist" tradition as myself, I do have a soft spot in my heart (Minnesota colleagues would probably say in my head) for psychoanalysis. So, the most honest and straightforward way to deal with Bouchard's complaint might be simply to admit that the evidence on Freud is inadequate and that Bouchard and I are simply betting on different horses. But I cannot resist the impulse to say just a bit more on this vexatious question, because while I am acutely aware of a pronounced (and possibly irrational) difference in the "educated prior" I put on Freud as contrasted with rubber band theory or labeling theory or whatever, I am not persuaded that my position is as grossly incoherent as it admittedly appears. Passing the question whether attempts to study psychoanalytic theory by the methods of experimental or differential psychology have on the whole tended to support rather than refute it (see, e.g., Fisher & Greenberg, 1977; Rapa-port, 1959; Sears, 1943; Silverman, 1976), my own view is that the best place to study psychoanalysis is the psychoanalytic session itself, as I have elsewhere argued in a far too condensed way (Meehl, 1970/1973e).

I believe that some aspects of psychoana-

lytic theory are not presently researchable because the intermediate technology required—which really means instruments-cum-theory—does not exist. I mean auxiliaries and methods such as a souped-up, highly developed science of psycholinguistics, and the kind of mathematics that is needed to conduct a rigorous but clinically sensitive and psychoanalytically realistic job of theme tracing in the analytic protocol. This may strike some as a kind of cop-out, but I remind you that Lakatos, Kuhn, Feyerabend, and others have convincingly made the point that there are theories in the physical and biological sciences that are untestable when first propounded because the theoretical and technological development necessary for making certain kinds of observations bearing on them had not taken place. It is vulgar positivism (still held by many psychologists) to insist that any respectable empirical theory must be testable, if testable means *definitively testable right now*.

But I do think that there is another class of consequences of psychoanalytic theory, close to the original "clinical connections" alleged by Freud, Ferenczi, Jones, Abraham, and others that does not involve much of what Freud called *the witch metapsychology*, where no complicated statistics are needed, let alone the invention of any *new* formal modes of protocol analysis. Here the problem is mainly that *none of us has bothered to carry out some relatively simple-minded kinds of analyses on a random sample of psychoanalytic protocols collected from essentially naive patients to whom no interpretations have as yet been offered*. This second category is, in my view, a category of research studies that we could have done, but have not done. *Example*: We can easily ascertain whether manifest dream content of a certain kind is statistically associated (in the simple straightforward sense of a patterned fourfold table) with such and such kinds of thematic material in the patient's subsequent associations to the dream. I would not even object to doing significance tests on a batch of such tables, but to explain why would unduly enlarge what is already an addendum.

I cheerfully admit, in this matter, to the presence of a large distance between my subjective personalistic probability (based on my

experiences as analysand and practitioner of psychoanalytic therapy) and the present state of the "intersubjective public evidence." That is what I mean by saying that Bouchard and I are betting on different horses. But one must distinguish, as I know from subsequent conversations that he does, between a criticism (a) that what *is* proper evidence *does* presently exist and is *adverse* to a conjecture and (b) an anti-Popperian claim that falsifiability in principle does not matter. If I thought (as does Popper) that Freudian theory was in principle not falsifiable, then I would have to confess to a major inconsistency. But I do think it is falsifiable, although I agree that *some parts* of it cannot *at present* be tested because of the primitive development of the auxiliary theories and the measurement technologies that would be jointly necessary.

A final point on this subject is one that I hesitate to include because it is very difficult to explain in the present state of philosophy of science, and I could be doing my main thesis damage by presenting a cursory and somewhat dogmatic statement of it. Nevertheless, having made the above statements about psychoanalytic theory and having contrasted it favorably with some of the (to me, trivial and flabby) theories in soft psychology, I fear I have an obligation to say it, however ineptly. Once one sees that it is inappropriate to conflate the concepts *rational* and *statistical*, then it is a fuzzy open question, in the present state of the metatheoretician's art, just when a mass of nonquantitative converging evidence can be said to have made a stronger case for a conjecture than the weak kinds of nonconverging quantitative evidence usually represented by the significance testing tradition. I say "when" rather than "whether," because it is blindingly obvious that *sometimes* qualitative evidence of certain sorts is superior in its empirical weight to what a typical social, personality, or clinical psychologist gets in support of a substantive theory by the mere refutation of the null hypothesis. Take, for instance, the evidence in a well-constructed criminal case, such as the evidence that Bruno Hauptmann was the kidnapper of the Lindbergh baby. I do not see how anybody who reads the trial transcript of the Hauptmann

case could have a reasonable doubt that he was guilty as charged. Yet I cannot recall any of the mass of data that convicted him as being of a quantitative sort (one cannot fairly except the serial numbers on the gold notes, they being not "measures" but "football numbers").

All of us believe a lot of things that we would not have the vaguest idea how to express as a probability value (*pace* strong Bayesians!) or how to compute as an indirect test of statistical significance. I believe, for instance, that Adolf Hitler was a schizotype; I do not believe that Kaspar Hauser was the son of a prince; I believe that the domestic cat probably was evolved from *Felis lybica* by the ancient Egyptians; I hold that my sainted namesake wrote the letter to the Corinthians but did not write the letter to the Hebrews; I am confident that my wife is faithful to me; and so forth. The point is really a simple one—that there are many areas of both practical and theoretical inference in which nobody knows how to calculate a numerical probability value, and nobody knows how to state the manner or degree in which various lines of evidence converge on a certain conjecture as having high verisimilitude. There are propositions in history (such as, "Julius Caesar crossed the Rubicon") that we all agree are well corroborated by the available documents but without any *t* tests or the possibility of calculating any, whereas Fisbee's theory of social behavior is only weakly corroborated by the fact that he got a significant *t* test when he compared the boys and the girls or the older kids and the younger kids on the Hockheimer-Sedlitz Communication Scale. Now I consider my betting on the horse of psychoanalysis to be in the same kind of ball park as my beliefs about Julius Caesar or the evolution of the cat. But, I repeat, this may be a terribly irrational leap of faith on my part. For the purposes of the present article and Bouchard's criticism of it, I hope it is sufficient to say that one could arguably hold that significance testing in soft psychology is a pretentious endeavor that falls under a tolerant neo-Popperian criticism, and could nevertheless enter his personalistic prediction that *when adequate tests become available to us, a sizable portion of psychoanalytic theory*

will escape refutation. So I do not think I am actually contradicting myself, but I am personalistically betting on the outcome of a future horse race.

A Reader's, Writer's, and Reviewer's Guide to Assessing Research Reports in Clinical Psychology

Brendan A. Maher
Harvard University

The Editors of the *Journal of Consulting and Clinical Psychology* who served between 1974 and 1978 have seen some 3,500 manuscripts in the area of consulting and clinical psychology. Working with this number of manuscripts has made it possible to formulate a set of general guidelines that may be helpful in the assessment of research reports. Originally developed by and for journal reviewers, the guidelines are necessarily skeletal and summary and omit many methodological concerns. They do, however, address the methodological concerns that have proved to be significant in a substantial number of cases. In response to a number of requests, the guidelines are being made available here.

Topic Content

1. Is the article appropriate to this journal? Does it fall within the boundaries mandated in the masthead description?

Style

1. Does the manuscript conform to APA style in its major aspects?

Introduction

1. Is the introduction as brief as possible given the topic of the article?
2. Are all of the citations correct and necessary, or is there padding? Are important citations missing? Has the author been careful to cite prior reports contrary to the current hypothesis?
3. Is there an explicit hypothesis?
4. Has the *origin* of the hypothesis been made explicit?
5. Was the hypothesis *correctly* derived from the theory that has been cited? Are other, contrary hypotheses compatible with the same theory?
6. Is there an explicit rationale for the selection of measures, and was it derived logically from the hypothesis?

Method

1. Is the method so described that replication is possible without further information?
2. **Subjects:** Were they sampled randomly from the population to which the results will be generalized?
3. Under what circumstances was informed consent obtained?
4. Are there probable biases in sampling (e.g., volunteers, high refusal rates, institution population atypical for the country at large, etc.)?
5. What was the "set" given to subjects? Was there deception? Was there control for experimenter influence and expectancy effects?
6. How were subjects debriefed?
7. Were subjects (patients) led to believe that they were receiving "treatment"?
8. Were there special variables affecting the subjects, such as medication, fatigue, and threat that were not part of the experimental manipulation? In clinical samples, was "organicity" measured and/or eliminated?
9. **Controls:** Were there appropriate control groups? What was being controlled for?
10. When more than one measure was used, was the order counterbalanced? If so, were order effects actually analyzed statistically?
11. Was there a control task(s) to confirm specificity of results?
12. **Measures:** For both dependent and independent variable measures—was validity and reliability established and reported? When a measure is tailor-made for a study, this is very important. When validities and reliabilities are already available in the literature, it is less important.
13. Is there adequate description of tasks, materials, apparatus, and so forth?
14. Is there discriminant validity of the measures?
15. Are distributions of scores on measures typical of scores that have been reported for similar samples in previous literature?
16. Are measures free from biases such as
 - a. Social desirability?
 - b. Yeasaying and naysaying?
 - c. Correlations with general responsivity?
 - d. Verbal ability, intelligence?
17. If measures are scored by observers using categories or codes, what is the inter-rater reliability?
18. Was administration and scoring of the measures done blind?
19. If short versions, foreign-language translations, and so forth, of common measures are used, has the validity and reliability of these been established?
20. In correlational designs, do the two measures have theoretical and/or methodological independence?

Representative Design

1. When the stimulus is a human (e.g., in clinical judgments of clients of differing race, sex, etc.), is there a *sample* of stimuli (e.g., more than one client of each race or each sex)?
2. When only one stimulus or a few human stimuli were used, was an adequate explanation of the failure to sample given?

Statistics

1. Were the statistics used with appropriate assumptions fulfilled by the data (e.g., normalcy of distributions for parametric techniques)? Where necessary, have scores been transformed appropriately?
2. Were tests of significance properly used and reported? For example, did the author use the p value of a correlation to justify conclusions when the actual size of the correlation suggests little common variance between two measures?
3. Have statistical significance levels been accompanied by an analysis of practical significance levels?
4. Has the author considered the effects of a limited range of scores, and so forth, in using correlations?
5. Is the basic statistical strategy that of a "fishing expedition"; that is, if many comparisons are made, were the obtained significance levels predicted in advance? Consider the number of significance levels as a function of the total number of comparisons made.

Factor Analytic Statistics

1. Have the correlation and factor matrices been made available to the reviewers and to the readers through the National Auxiliary Publications Service or other methods?
2. Is it stated what was used for communalities and is the choice appropriate? Ones in the diagonals are especially undesirable when items are correlated as the variables.
3. Is the method of termination of factor extraction stated, and is it appropriate in this case?
4. Is the method of factor rotation stated, and is it appropriate in this case?
5. If items are used as variables, what are the proportions of yes and no responses for each variable?
6. Is the sample size given, and is it adequate?
7. Are there evidences of distortion in the final solution, such as singlet factors, excessively high communalities, obliqueness when an orthogonal solution is used, linearly dependent variables, or too many complex variables?
8. Are artificial factors evident because of inclusion of variables in the analysis that are alternate forms of each other?

Figures and Tables

1. Are the figures and tables (a) necessary and (b) self-explanatory? Large tables of nonsignificant differences, for example, should be eliminated if the few obtained significances can be reported in a sentence or two in the text. Could several tables be combined into a smaller number?
2. Are the axes of figures identified clearly?
3. Do graphs correspond logically to the textual argument of the article? (E.g., if the text states that a certain technique leads to an *increment* of mental health and the accompanying graph shows a *decline* in symptoms, the point is not as clear to the reader as it would be if the text or the graph were amended to achieve visual and verbal congruence.)

Discussion and Conclusion

1. Is the discussion properly confined to the findings or is it digressive, including new post hoc speculations?
2. Has the author explicitly considered and discussed viable alternative explanations of the findings?
3. Have nonsignificant trends in the data been promoted to "findings"?
4. Are the limits of the generalizations possible from the data made clear? Has the author identified his/her own methodological difficulties in the study?
5. Has the author "accepted" the null hypothesis?
6. Has the author considered the possible methodological bases for discrepancies between the results reported and other findings in the literature?

Many detailed responses to a first draft were reviewed. Particular acknowledgment is due to Thomas Achenbach, George Chartier, Andrew Comrey, Jesse Harris, Mary B. Harris, Alan Kazdin, Richard Lanyon, Eric Mash, Martha Mednick, Peter Nathan, K. Daniel O'Leary, N. D. Reppucci, Robert Rosenthal, Richard Suinn, and Norman Watt.

Requests for reprints should be sent to Brendan A. Maher, Department of Psychology and Social Relations, Harvard University, Cambridge, Massachusetts 02138.

This material may be reproduced in whole or in part without permission, provided that acknowledgment is made to Brendan A. Maher and the American Psychological Association.

Association for Advancement of Behavior Therapy

TWELFTH ANNUAL CONVENTION
CONRAD HILTON **CHICAGO, ILLINOIS**
November 17-19, 1978

PRE-CONVENTION INSTITUTES - NOVEMBER 16, 1978
*Intensive 5-hour sessions with leaders in the field, limited
to thirty participants to insure interaction*

**WORKSHOPS - SYMPOSIA - INVITED ADDRESSES
POSTER SESSIONS**

Topics will include:

Treatment of Sexual Dysfunction
Treatment of Addictive Behaviors
Assertion and Social Skills Training
Behavioral Medicine - Treatment of Depression
Self-Control and Cognitive Behavior Modification
Behavior Modification in Business and Industry
Behavioral Approaches to Marital and
Interpersonal Problems

8-HOUR BASIC COURSE IN BEHAVIOR THERAPY
EMPLOYMENT PLACEMENT BUREAU
FILM PROGRAM - EXHIBIT AREA

SOCIETY OF BEHAVIORAL MEDICINE
organizational meeting

Continuing Education Credit including Category I AMA credit for the
Physicians' Recognition Award (17 hours) will be available.

*For a copy of the Convention Program Booklet when it is
published in September please contact:*

Psychosocial Treatment of Chronic Mental Patients

Milieu vs. Social-Learning Programs

Gordon L. Paul and Robert J. Lentz

Paul and Lentz have spent seven years evaluating alternative methods for treating chronic patients. Here is the definitive report of their startling results.

"There has not been previously available to the field such a matchless rigor in experimental design, so clear a specification of treatment programs, so lengthy a period of in-hospital observation and community after-care follow-up, such precise measurement of dependent variables, and such striking treatment results." —Norman Garnezy, University of Minnesota \$22.50

Career Opportunities for Psychologists

Expanding and Emerging Areas
Paul J. Woods

May 1976. 26 chapters, 320 pages.
\$5. ISBN 0-912704-03-9.

For the undergraduate and graduate student in psychology.

For the psychologist thinking about changing careers or expanding his/her areas of specialization.

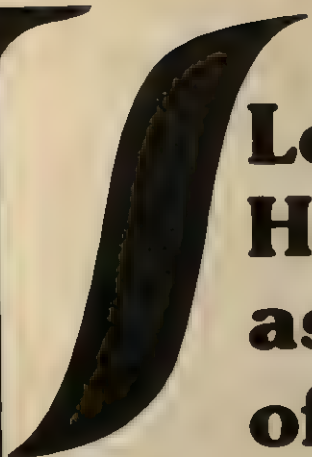

This book reviews the current employment picture for psychologists in academia; explores innovative career opportunities in such areas of employment as health research, population and environment, industry, forensic psychology, engineering psychology, criminal justice, drug and alcohol abuse, public affairs psychology, program evaluation, architecture, and more; includes "how to" chapters on using job placement mechanisms, writing a vita, and writing letters to prospective employers; provides brief job descriptions on psychologists already serving in innovative or nontraditional roles.

Learned Helplessness as a Model of Depression

**Special issue of the
Journal of Abnormal Psychology,
February 1978.**

The issue serves as a forum to investigate the validity and adequacy of the learned helplessness model of depression in humans and includes both critical and supportive theoretical and empirical articles with comments.

L. Rowell Huesmann is guest editor. Richard A. Depue, Martin E. P. Seligman, Charles G. Costello, Robert C. Smolen, and Alexander M. Buchwald are among the contributors.

Copies of the special issue are available at \$6 each, prepaid. Discounts on bulk orders are also available. To order single copies or for more information on bulk orders write:

Evaluation of Psychological Service Delivery Programs

Special Issue of Professional Psychology

Evaluation of Psychological Service Delivery Programs is the title of a special November, 1977 issue of Professional Psychology. Editor Allan Barclay and guest Co-editors Bob and Evelyn Perloff have assembled a distinguished collection of articles that brings readers up to date on the evaluation of psychological services. The issue addresses the need to justify the effectiveness of service delivery programs not only in terms of cost but more importantly in terms of human benefits.

Sample Topics and Contributors

A sample of the topics and contributors appearing in this issue includes: Theodore Blau on quality of life; Nicholas Cummings on psychotherapy; Howard Blane on alcoholism; S. B. Sells and associates on drug abuse, and NIMH's Bertram Brown, Benjamin Liptzin and James Stockdill on the federal view of mental health program evaluation.

Ordering Information

Single copies of the issue are available from the Order Department at APA for \$5 each. All orders \$25 or under must be prepaid. Please make checks payable to APA. Send your orders to:

For the First Time...

An easy reading, practical, step by step guide to

A must for

- Full and Part-time private practitioners.
- Those who have ever even considered entering private practice.

"Reduces the chance of failure or disappointment."

An entertaining, well organized book complete with worksheets, plans, and practical approaches to the everyday "nuts and bolts" business aspects of private practice.

MARK H. LEWIN, an ABPP Diplomate, distinguished author and editor, and founder of a thriving independent psychological service center, gives step-by-step procedures for:

- Assessing your readiness for private practice
- Preplanning the practice
- Setting up the office
- Developing new referrals
- Managing your time
- Effective use of lawyers and accountants
- Evaluating the practice as it develops
- Budgeting, fee setting, controlling costs and tax expenses

Barbara R. Richman, *Production Editor*

Robert J. Hayward, *Advertising Representative*

Juanita Brodie, *Subscription Manager*

The *Journal of Consulting and Clinical Psychology* publishes original contributions on the following topics: (a) the development, validity, and use of techniques of diagnosis and treatment in disordered behavior; (b) studies of populations of clinical interest, such as hospital, prison, rehabilitation, geriatric, and similar samples; (c) cross-cultural and demographic studies of interest for the behavior disorders; (d) studies of reliability and of its assessment and development where these have a clear bearing on problems of consulting and clinical psychology; or (e) case studies pertinent to the preceding topics. In order to improve the use of journal resources it has been agreed by the two Editors concerned that the *Journal of Consulting and Clinical Psychology* will no longer consider manuscripts dealing with the etiology or descriptive pathology of abnormal behavior, and the *Journal of Abnormal Psychology* will no longer consider articles dealing with the diagnosis or treatment of abnormal behavior. Articles that appear to have a significant contribution to both of these broad areas may be sent to either journal for editorial decision. Papers of a theoretical nature will also be considered within the space limitations of the journal.

Manuscripts: Submit manuscripts in triplicate to the Editor-elect, Sol L. Garfield, Department of Psychology, Washington University, St. Louis, Missouri 63130 according to instructions provided elsewhere in the journal. Authors submitting a manuscript previously considered for publication in another APA journal are invited to inform the Editor, who will then seek to obtain independent reviews, thus avoiding the possibility of repeated reviewing by the same consultant.

Copyright and Permission: All rights reserved. Written permission must be obtained from the American Psychological Association for copying or reprinting text of more than 500 words, tables, or figures. Permissions are normally granted contingent upon like permission of the author, inclusion of the APA copyright notice on the first page of reproduced material, and payment of a fee of \$10 per page, table, or figure of APA material. Permission and fees are waived for authors who wish to reproduce their own material for personal use; fees only are waived for authors who wish to use their own material commercially. Abstracting is permitted with credit to the source. Libraries are permitted to photocopy beyond the limits of U.S. copyright law: (1) those post-1977 articles that carry a code at the bottom of the first page, provided the per copy fee indicated in the code is paid through the Copyright Clearance Center, P.O. Box 765, Schenectady, NY 12301; (2) pre-1978 articles without fee. Instructors and educational institutions are permitted to photocopy isolated articles for noncommercial classroom or library reserve use without fee. Address requests for permission to the Permissions Office, APA, 1200 Seventeenth Street, N.W., Washington, D.C. 20036.

Subscriptions: Subscriptions are available on a calendar year basis only (January through December). Nonmember rates for 1978: \$32 domestic, \$34 foreign, \$6 single issue. APA member rate: \$16. Write to Subscription Section, APA.

Reprints: Authors may order reprints of their articles from the printer when they receive proofs.

Back Issues and Back Volumes: For information regarding back issues or back volumes write to Order Department, APA.

Microform Editions: For information regarding microform editions write to any of the following: Johnson Associates, Inc., P.O. Box 1017, Greenwich, Connecticut 06830; University Microfilms, Ann Arbor, Michigan 48106; or Princeton Microfilms, Princeton, New Jersey 08540.

Change of Address: Send change of address notice and a recent mailing label to the attention of the Subscription Section, APA, 30 days prior to the actual change of address. APA will not replace undelivered copies resulting from address changes; journals will be forwarded only if subscribers notify the local post office in writing that they will guarantee second-class forwarding postage.

Published bimonthly (beginning in February) in one volume per year by the American Psychological Association, Inc., 1200 Seventeenth Street, N.W. Washington, D.C. 20036. Printed in the U.S.A. Second-class postage paid at Washington, D.C., and at additional mailing offices.

Personality Traits and Environmental Variables as Independent Predictors of Posthospitalization Outcome

George A. Clum

Virginia Polytechnic Institute and State University

A set of predictor variables, identified as intrapsychic, and a second set, identified as environmental, were examined in a multiple regression analysis as to their independent contribution in predicting posthospitalization adjustment. The analyses indicated that level of adjustment at baseline hospitalization was the most salient prognostic variable. Significant others' expectations for the patients' self-help performance contributed independently to a follow-up criterion of total symptomatology as rated by the significant other. The results provide moderate support for the hypothesis that environmental as well as intrapsychic variables are important prognostic indicators.

A recent review of prognostic factors of hospitalized psychiatric patients (Clum, 1975b) has shown that two types of variables, intrapsychic and environmental, can be hypothesized to be independent predictors of posthospital outcome. This conclusion was largely inferential, however, and no substantive data exist that demonstrate the independent contribution of each set of variables. To accomplish this, three conditions must be met: (a) A set of predictor variables, identified as intrapsychic, must be found to *predict* posthospital outcome; (b) a set of predictor variables, identified as environmental, must be found to predict posthospital outcome; and (c) both sets must contribute independent variance to the criterion in a multiple regression format. In line with the previous definition of these variables, intrapsychic variables include any "measurable cognitive or personality characteristics the patient exhibits. Environmental variables are defined as socio-

psychological phenomena within the patient's life space, but external to the patient himself" (Clum, 1975b, p. 416).

One example that may clarify the problem involves the relationship between marital status and prognosis. The personality trait view suggests that individuals who are single and socially withdrawn will not be selected as marriage partners and will tend to have a bad prognosis. Being single has been found to be related to an individual's continued stay in a mental institution and also to poor social adjustment on release from the hospital (Clum, 1975b). In contrast, the environmental view suggests that being married acts as a buffer that leads to a greater likelihood of the patient having a good prognosis. People who are married have a definite role in the family, whereas people who are single are neither the homemaker nor the breadwinner and hence have roles secondary to the functioning of the family. The press to perform will accordingly be less for the single individual and might be anticipated to lead to poorer performance for such people according to an expectation hypothesis.

To determine whether the relationship between single status and poor prognosis is due to a selection process or to a buffer hypothesis, the initial level of patient dysfunction must be controlled. If it can be shown that single individuals do not exhibit more disturbance

than married individuals on admission to a hospital but that they do exhibit a poorer prognosis, the buffer hypothesis would be supported.

Another example that can be addressed to the question of independent contribution to prognosis would be that of expectations and outcome. The personality trait view would predict that the more disturbance exhibited by the individual, the lower would be the expectations, resulting in a poor prognosis; that is, level of disturbance would determine level of expectations. The environmentalist would predict outcome from expectations independent of level of disturbance.

The relative importance of these two sets of variables has been studied previously in relation to in-hospital criteria of length of hospitalization and rated improvement at discharge (Clum, 1975a). Although Clum's (1975a) study supported the hypothesis that environmental variables are predictive of length of hospitalization, it must be considered an inconclusive test. Length of hospitalization is a relatively weak criterion because of its fluctuation on the basis of administrative considerations and because of the fact that in a short-stay hospital such as the one in his study, the criterion variance is severely truncated. Accordingly, the present study expands this analysis using a criterion of rated adjustment 1 year after initial hospitalization.

Method

Subjects

Subjects in the present study ($N = 79$) included all patients admitted to the University of Virginia psychiatric service who were also available for follow-up evaluation 1 year after admission. This sample represented a severely truncated subsample (50%) of the subjects who had completed all baseline data, a reduction of subjects which, however, is comparable to other studies using mailings and phone calls to obtain follow-up data. A comparison of the two groups, however, revealed no differences on variables of marital status, age, race, social class, and initial level of symptomatology on five symptom factors. The subjects were between the ages of 16 and 65 and included only those who did not have a diagnosis of organic brain damage.

Predictors

At the time of hospitalization, each patient was administered a biographical inventory, the Life Change Inventory (described previously by Clum, 1976), and a measure of expectations for improvement. Information culled from the biographical inventory included total time previously spent in mental hospitals, education, income, marital status, age, and number of friends. The patients' expectations were derived from the Katz Adjustment Scales (Katz & Lyerley, 1963).

A significant other also rated his/her expectations for the patient's performance once the patient returned home from the hospital. Two measures of expectations were obtained—one regarding the patient's performance on self-help tasks, the other regarding the patient's social adjustment.

Criterion Measures

Two criteria were used—total number of symptoms as noted by the patient and total number of symptoms as noted by the significant other. The Katz Adjustment Scales were used to evaluate symptomatology.

Procedure

At the time of hospitalization, patients were asked to complete all research forms. A significant other (spouse, parent, relative, or friend) who was familiar with the patient's adjustment in the month prior to hospitalization was also asked to complete the research instruments. One year later the patient and the same significant other were again contacted, and the same forms were readministered. The sample was then divided randomly into validation and hold-out samples to determine the stability of the results.

Results

Patient-Related Symptomatology

Both environmental and personality trait measures were entered into a stepwise multiple regression equation in order to assess the independent contribution of each variable to a criterion of total symptomatology as rated 1 year after hospitalization. As Table 1 indicates, only total symptomatology at baseline, time in mental hospital, and education contributed independently to patient-rated total symptomatology at the 1-year follow-up. Further, only total symptomatology at baseline was found to contribute independently to the criterion in the hold-out cross-validation group.

Table 1
Regression Analysis of Predictor Variables at Hospitalization to Patient-Rated Total Symptomatology at 1-Year Follow-Up

Predictor variable	Sample

^c Environmental.

^d Married = 1; all others = 2 (complex).

* $p = .05$.

** $p = .01$.

Stress was not found to be related to the criterion. However, significant others' expectations for the patient's performance on self-help tasks correlated in the expected direction with outcome but did not contribute independently to its predictions.

Significant-Other-Rated Symptomatology

The regression analysis of significant-other-rated total symptomatology at the 1-year follow-up (see Table 2) demonstrated that baseline total symptomatology, significant others' expectations for self-help, number of friends, marital status, and patients' baseline expectations were the only variables of those examined that contributed independently to the criterion. Significant others' expectations of self-help were significant at the .01 level, supporting the importance of expectations as a prognostic variable, independent of personality traits. Marital status was also reliably re-

lated to significant others' ratings of total symptomatology, again, in a negative direction. This was contrary to predictions. Of these five predictors only total baseline symptomatology and significant others' expectations cross-validated as independent contributors to the criterion.

The vast majority of previous research has found single people to have poorer prognoses. Since most of these studies were conducted on predominantly schizophrenic populations, it was decided to reanalyze the relationship between marital status and outcome separately for schizophrenic and schizoid personality patients and all other diagnostic groups. Pearson correlation coefficients were computed between marital status and total symptomatology at follow-up for patients diagnosed as schizophrenic or schizoid personality. The results indicated that marital status and total symptomatology at follow-up were related ($r = .41$ between marital status and significant others'

ratings; $r = .43$ between marital status and patients' ratings) in a generally positive direction, although not reaching significance due to the small sample size (8). Thus, for this subgroup of patients, a single status led to a poorer prognosis, as was previously predicted.

Discussion

The present study sought to determine whether environmental factors are of independent prognostic significance when considered conjointly with personality trait variables. A multiple regression format in which both types of predictors were considered was used to make this determination.

The results provided partial support for the hypothesis that predictor variables representative of both classes of variables would contribute independent predictor variance. Specifically, initial level of symptomatology was consistently related to the criterion. In addition,

significant others' expectations for self-help were related to total symptomatology as rated by the significant other but not as rated by the patient. This provides moderate support for the import of an environmental factor of others' expectations as an independent prognostic variable. Heretofore, it has been unclear whether the relationship of expectations to outcome was attributable to the fact that others' expectations were lower for those individuals whose adjustment was poor. It is arguable whether poor prognosis in this case was a function of the expectations or the already poor adjustment. The fact that expectations for self-help were not independently related to patients' ratings of symptomatology suggests that for this criterion the impact of expectations is determined largely by its relationship to initial level of symptoms.

No other prognostic variable, either personality or environmental, cross-validated.

This is especially confusing with regard to marital status, since this variable has been most consistently related to prognosis (Clum, 1975b). The vast majority of these studies, however, included Veterans Administration or state hospital patients, most of whom were schizophrenic and chronic. In the present study a marital status of married was positively correlated with significant-other-rated symptomatology, as compared with a negative relationship in most other studies. Since most of the patients in the present study were neither schizophrenic nor chronic, it was decided to analyze the relationship between marital status and outcome separately for those patients diagnosed as schizophrenic or schizoid and those with all other diagnoses. The results confirmed the finding of previous studies: Married status was related to a better outcome for the schizophrenic and schizoid subgroup. It is possible, therefore, that diagnosis is a moderator of the marital status-outcome relationship, rendering marital status an even more powerful prognostic variable. Whether it contributes independently to outcome for schizophrenic patients still remains an unanswered question.

The environmental variable of life stress was not found to be of any reliable consequence. However, in another study (Clum, 1976), it was demonstrated that whereas life changes prior to hospitalization were unrelated to symptomatology at follow-up, they were related to the level of symptoms at the time of hospitalization. Similarly, life changes subsequent to hospitalization were predictive of level of symptomatology 1 year after hospitalization. This supports Rahe's (1972) notion that stress only in the preceding year is predictive of symptomatology.

Implications

The implications of this study are twofold. First, the question of prognosis that confronts the clinician is related to decisions regarding disposition. For example, if a patient can be predicted to have a poor prognosis, the insistence on further follow-up treatment could

be increased. Decisions to continue hospitalization for a longer period of time or until such time as those factors predictive of outcome have been modified could be affected.

The second implication concerns those areas targeted for change. Since previous studies have focused on intrapsychic variables and have related these to outcome, the focus of the clinician has remained at effecting changes in the patient's personality. With the addition, in the present study, of the importance of expectations and possible role models as independent predictors of outcome, a new direction for targets for change should be forthcoming. Specifically, attention should be paid to changing the patient's families' expectations for performance, such that higher demands on the patients performance of self-help tasks should be emphasized. The importance of assuming a significant role in the family as a breadwinner or homemaker appears specific to schizophrenic patients. For this group, accordingly, the importance of developing significant social roles would seem to be a target for therapeutic intervention. In contrast, being married was found to be a negative prognostic factor for nonschizophrenic patients. Accordingly, affecting a more positive relationship within the marital context should receive greater attention in this group.

Rorschach Developmental Level and Intelligence Factors

Roger P. Greenberg

Department of Psychiatry
State University of New York
Upstate Medical Center, Syracuse

Gilbert F. Cardwell

DePaul University

This study sought to provide a more complete exploration of the relationship between Rorschach developmental level scores and intelligence than has appeared to date in the literature. Factor scores for both Wechsler Adult Intelligence Scale and Rorschach measures were used in comparing test protocols obtained from 86 psychiatric inpatients. Results reaffirmed a relationship between intellectual level and developmental level. Further, the relationship was found to be of a general nature. It did not rely specifically on verbal, perceptual, or memory factors. Results also indicated that the relationship held for females as well as males.

On the basis of Werner's (1948) developmental theory, Friedman (1953) derived a Rorschach measure of developmental level (DL). Goldfried, Stricker, and Weiner (1971) have reviewed a large number of the studies making use of this index and concluded that Friedman's scoring of the Rorschach results is a good measure of the DL of functioning. Findings indicate impressively stable and theoretically consistent age effects, theoretically consistent differences among pathological groups, correlations with the degree of regression among schizophrenics, and successful prediction of superior interpersonal functioning among high-scoring groups.

The relationship between DL and intelligence has been one issue of discussion in the literature. Werner (1948) speculated that mental development proceeds in the direction of increasing differentiation and hierarchical integration. This view offers a developmental framework for Ainsworth and Klopfer's (1954) hypothesis that "vague, global perception reflects a relatively low level capacity and . . . the more refined and differentiated

the perception the higher the level of intelligence" (p. 353). Thus, viewing the DL scoring of the Rorschach as an indicator of general cognitive functioning suggests a relationship with measures of intellectual ability.

In general, the literature has strongly supported the idea of such a relationship. For example, Goldfried (1962) found significant correlations between DL and IQ scores in a sample of male neuropsychiatric patients. Similarly, Blatt and Allison (1963) found IQ scores to be significantly related to developmentally high Whole Response scores in samples of graduate students and neuropsychiatric patients (Allison & Blatt, 1964; Blatt & Allison, 1963). Friedman and Orgel (1964) found a DL-IQ association in paranoid schizophrenics. They did not find the relationship in groups of catatonics, hebephrenics, neurotic brain-damaged patients, or normals. However, as Kissel (1965) has noted and demonstrated, the failure to find a relationship probably resulted from Friedman and Orgel's use of percentage scores rather than from an inherent lack of relationship between DL and intelligence.

Kissel (1965) did find the predicted relationship in a sample drawn from a child guidance clinic, and there has been a report of an association between DL and mental age in children (O'Neill, O'Neill, & Quinlan, 1976). Gerstein, Brodzinsky, and Reiskind

(1976) also found the general relationship in a group of white children. Interestingly, however, in looking at children of below-average intelligence, they discovered that black subjects produced higher DL scores than did their white counterparts. They raised the possibility that a developmental-structural analysis of the Rorschach may provide a more realistic assessment of the cognitive capacity of some black children than do standard IQ tests.

Thus, there is now consistent evidence of a link between a Rorschach measure of cognitive development and tests of intellectual ability. However, since measures of intelligence are usually a composite of different kinds of abilities, Goldfried et al. (1971) suggested that it would be of value to specify which aspects of intellectual functioning are related to DL. The goal of the present article is to state more exactly the nature of the relationship between DL and intelligence. This goal is pursued by examining the relationship between two independent factors underlying DL and three independent factors underlying performance on the Wechsler Adult Intelligence Scale (WAIS). These factors are derived from previous factor analytic studies of the WAIS and a project of our own that examined the factor structure among Rorschach cards scored for DL.

Specifically, studies of the WAIS have extracted three factors in addition to a dominant general factor. These three dimensions have been labeled *Verbal Comprehension*, *Perceptual Organization*, and *Memory* (or *Freedom from Distractibility*) (Berger, Bernstein, Klein, Cohen, & Lucas, 1964; Cohen, 1957a, 1957b). Scores for the factors can be obtained by adding the scaled scores of the WAIS subtests making up each factor.

A construct validity study of the DL measure revealed two independent factors among Rorschach cards scored for DL (Cardwell & Greenberg, Note 1). One factor was the composite DL score obtained by adding up the subject's DL scores on each of the 10 Rorschach cards. The second factor was obtained by taking the difference between a subject's DL scores on two contrasting sets of four cards (i.e., DL score on Cards 3, 4, 5, and 6 minus the DL score on Cards 7, 8, 9, and 10).

In sum, the present study concerns the relationship between three distinct sources of variation within IQ data and two distinct sources of variation within the DL measure. This permits an examination of the total pattern of correlations among the five measures and a look at the number and form of dimensions that may contribute to covariation. If one predicts a nonspecific general factor underlying both DL and IQ, a relationship across all IQ factors and DL scores would be expected. This is the implication of Ainsworth and Klopfer's (1954) view. Alternatively, a more specific relationship would be suggested if DL dimensions were related to only verbal, perceptual, or memory factors on the WAIS.

In addition to providing a more thorough analysis of the relationship between IQ and DL, the present study also permits an examination of sex differences in the relationships. Previous studies of the DL construct have largely not included female subjects (Goldfried et al., 1971).

Method

Data used in the study were obtained from the file of a medical center psychology service. All Rorschach tests in the file had been administered and scored for DL by faculty members with extensive Rorschach experience or by psychology interns under the direct supervision of these faculty members. The interscorer reliability of the DL system has been found to be quite high, ranging from 89.7 to 95.5 (Friedman, 1953; Goldfried et al., 1971).

In selecting protocols for study, all referrals from the hospital's psychiatric inpatient service over a 7-year period were reviewed, and 86 records (57 women and 29 men) met the following criteria for study: (a) an available summary sheet listing developmental scoring for each card, (b) the production of at least one response to each card, and (c) an available summary sheet of WAIS subtest scores. The mean age of the sample was 29.1, with a range of 16 to 68 years. Subjects carried psychiatric diagnoses from all major categories (psychoses, personality disorders, psychoneuroses). Patients with a diagnosis of organic brain syndrome were excluded from the sample.

Friedman applied Werner's "orthogenetic principle" in the development of his scoring system. Werner (1957) holds that with increasing maturity, mental functioning "proceeds from a state of relative globality and lack of differentiation to a state of increasing differentiation, articulation, and hierarchic integration" (p. 126). Friedman's system, which attempts to measure such changes in perceptual func-

tioning, uses only structural and organizational aspects of the percept. Rorschach responses are first scored for location (whole or detail) and are then placed into one of six categories. The categories represent increasing levels of differentiation and integration. They are labeled (in order of increasing maturity) *amorphous* (*a*), *minus* (*-*), *vague* (*v*), *mediocre* (*m*), *plus* (*+*), and *plus-plus* (*++*) responses. A detailed presentation of the scoring criteria is presented by Friedman (1952, 1953) and Goldfried et al. (1971).

For the present study, each response given to the Rorschach was assigned a value between 1 and 12 according to the corresponding developmental level of maturity. All responses to a single card were then summed, and this total was divided by the number of responses given to that card. The weightings used for each response are as follows: $W_a = 1$; $D_a = 2$; $W_- = 3$; $D_- = 4$; $W_v = 5$; $D_v = 6$; $D_m = 7$; $W_m = 8$; $D_+ = 9$; $W_+ = 10$; $D_{++} = 11$; $W_{++} = 12$.

The order of the major categories amorphous through plus-plus follows directly from Friedman's interpretation of Werner. The relative rankings of whole and detail categories is consistent with Werner's orthogenetic principle and parallels the developmental trends reported by Friedman, Hemmendinger, and Siegel (cited in Phillips & Smith, 1953). We might also add that our 12-point ranking system represents a more differentiated and congruent quantitative translation of Friedman's scoring system than has been used before. For example, Becker (1956) used only a 6-point system by sometimes ignoring the distinction between whole and detail responses and by arbitrarily grouping minus, vague, and amorphous responses in some categories.

Consistent with the factor analytic studies of the WAIS (Berger et al., 1964; Cohen, 1957a, 1957b), three factor scores were derived by summing the total scaled scores of the appropriate WAIS subtests: Verbal Comprehension (Information, Comprehension, Similarities, and Vocabulary), Perceptual Organization (Picture Completion, Block Design, and Object Assembly), and Memory (Arithmetic, Digit Span, and Digit Symbol).

Results and Discussion

As an initial step in the analysis, covariance matrices were estimated for the five variables (three WAIS factors and two DL factors) separately for each sex. Box's (1949) technique was used in comparing these matrices, and this test produced an F ratio less than one, indicating little difference between the pattern of correlations for male and female subjects. This finding is in line with previous research, indicating that the DL construct can be meaningfully and consistently applied to both sexes (Cardwell & Greenberg, Note 1).

Table 1
Correlations of DL Factors with WAIS Factors and Full Scale IQ

WAIS factor	DL factor	
	1	2
Verbal	.40**	.35**
Memory	.28**	.21*
Perceptual	.34**	.28**
Full Scale IQ	.40**	.35**

Note. WAIS = Wechsler Adult Intelligence Scale; DL = developmental level.

* $p < .05$.

** $p < .01$.

The data were then combined across sexes, and the five-variable Pearson product-moment correlation matrix was estimated. The correlations between the three WAIS factors and the two DL factors from this matrix are presented in Table 1 along with the correlations between Full Scale IQ and the two DL factors.

As can be seen the correlations are all positive, significant, and of similar magnitude. Bartlett's (1941, 1947) test of complete independence between two sets of data was applied to correlations between WAIS and DL factors, and the result was significant, $\chi^2(6) = 44.74$, $p < .001$. The correlations between Full Scale IQ and the DL factors were also significant ($p < .01$). These results reaffirm previous research findings of a relationship between DL and intellectual measures.

To help answer questions concerning the specificity of this relationship, canonical correlations were estimated (Morrison, 1967). This technique attempts to identify sources of common variance between two sets of measures by estimating weighted combinations of the variables that are most strongly correlated. After one such dimension is specified, its effects are removed from the matrix of correlations. Additional canonical variables, which are independent of the first dimension, can then be identified among the residual correlations. Each time a dimension is extracted from the matrix, Bartlett's test of complete independence is reapplied to the residual correlation matrix until a nonsignificant result indicates that all common variance has been accounted for.

Table 2
Loadings for Canonical Roots, Canonical Correlations, and Significance Tests Between WAIS and DL Factors

Factor and test	Loadings for canonical roots	
	First	Second
WAIS		
Verbal	.761	.052
Memory	.474	-.725
Perception	.443	.686
DL		
1 (total score)	.869	.158
2	.684	.170
r	.611	.265
Bartlett's test (χ^2)	44.74**	6.59*

Note. WAIS = Wechsler Adult Intelligence Scale;

DL = developmental level.

* $p < .025$ ($df = 2$).

** $p < .001$ ($df = 6$).

Applied to the correlations between WAIS and DL factors, this technique produced the results summarized in Table 2.

A maximum of two canonical correlations is possible in these data, and both were significant. The first and most important dimension related, with essentially equal loading, the sum of the three WAIS factors to the sum of the two DL factors and produced a correlation of .61. This result strongly supports the notion of a nonspecific general factor as the most important source of covariance between WAIS and DL variables. Among WAIS variables, such a dimension appears very similar to Spearman's (1927) construct of "general intelligence (g).". Stern (1956) has conceptualized Spearman's g as a property of the mind that determines its capacity for "collective coupling" of separate intellectual factors. In essence, his discussion, much like discussions of the DL construct, focuses on an individual's ability to effectively integrate differentiated (mental) systems. Thus, differentiation and integration seem to be key concepts for both a theory of g and a theory of DL. As already noted, these concepts are also consonant with Ainsworth and Klopfer's (1954) view of a relationship between perceptual differentiation and level of intelligence.

In addition, it is not surprising to find that a measure based on Rorschach responses is associated with verbal abilities as well as perceptual skills. Indeed, numerous factor analytic studies of the Rorschach have shown that verbal abilities play a significant role in the style and quality of Rorschach responses given (Murstein, 1965).

The second canonical variable found in the present study accounted for substantially less common variance and produced a correlation of only .265. However, Bartlett's test revealed that this correlation is significant. The loadings indicate that within the patient sample studied, there was a tendency for high DL factor scores to be associated with high WAIS perceptual factor scores and low memory factor scores.

Overall, then, the present findings reaffirm a relationship between intellectual and psychological developmental factors in a psychiatric population. Other statements about the relationship can now also be made—namely, that it is largely of a general nature; it does not rely specifically on verbal, perceptual, or memory factors; and it applies to females as well as males.

Life Event Scales: Psychophysical Training and Rating Dimension Effects on Event-Weighting Coefficients

Arthur A. Stone and John M. Neale
State University of New York at Stony Brook

Subjects chosen randomly from the community ($N = 54$) responded to questionnaires and rated either "social readjustment" or "stressfulness" for the events in the Social Readjustment Rating Scale. Some subjects were given psychophysical training before rating the events. The training did not have a significant effect on the ratings. However, stressfulness ratings were consistently higher than those of social readjustment, and the data suggest that this effect interacted with the events rated. The interaction may mean that choice of event dimension influences the ability to predict a dependent measure from weighted life events.

The systematic scaling of life events, introduced by Holmes and Rahe (1967), was a major breakthrough in quantifying the relationship between life events and both physical and psychiatric illness. These investigators used Stevens' (1974) technique of magnitude estimation to determine the amount of "social readjustment" that certain events would cause for an "average" person, regardless of the desirability of the event. Each subject was given a three-paragraph explanation of the rating task and then estimated the magnitude of social readjustment that each event would require. The original event coefficients, so-called since they were used to multiplicatively weight the occurrence of events, were produced by a "sample of convenience" of 394.

Results of investigations using events weighted by Holmes and Rahe's (1967) coefficients are plentiful. Weighted event scores have been used to predict sudden cardiac arrest (Rahe & Lind, 1970), time of myocardial infarction (Rahe & Paasikivi, 1971; Theorell & Rahe, 1971), occurrence of bone fractures (Tollefson, 1972), scholastic achievement

(Harris, 1973), disease and illness rates (Gunderson & Rahe, 1974), slight colds and fevers (Holmes & Holmes, 1970), and depression (Paykel, 1973). Though only partial, this list illustrates the diverse usage that this method has recently enjoyed. The majority of these studies have demonstrated modest, positive correlations between life event scores and criterion measures.

In this article we address several issues concerning Holmes and Rahe's (1967) method. First, will a sample of subjects randomly selected from the community produce the same coefficients as the original sample? Second, given the brief instructions used by Holmes and Rahe, does practice with matching numbers to lines and lines to numbers as opposed to no training affect the coefficients? Third, does asking a subject to rate "stressfulness," a term that incorporates the concept of desirability rather than social readjustment, affect the ratings? If any of these variables are found to significantly affect the data, then we must address the question of what the implications are for investigators who must choose among the available sets of event weightings.

Method

Subjects

One hundred households were randomly selected from the county telephone directory. Each was then randomly assigned to one of four experimental conditions such that there were 25 households in each.

Households were sent a letter of introduction, a payment of \$2, and, depending on experimental assignment, one of four questionnaires. The enclosed directions stated that any adult member of the family was eligible to complete the form. Several follow-up reminders were sent if the questionnaire was not returned within 2 weeks. The final sample consisted of 54 people; all respondents save 1 were white, 76% were male, and most were considered middle class based on income and education.

All subjects completed magnitude estimation of the 43 items found on the Holmes and Rahe Social Readjustment Rating Scale (SRRS; Holmes & Rahe, 1967). The ratings were done in one of four conditions and formed a 2 × 2 factorial design. The first factor was whether the questionnaire incorporated a magnitude-estimation training procedure prior to filling out the SRRS. The training condition consisted of matching numbers to line lengths ranging from .3 cm to 30.0 cm and drawing lines to represent numbers ranging from 3 to 300. Each of these tasks was composed of two parts: a page with detailed instructions explaining how to use numbers and line lengths to represent relative magnitudes, followed by 13 number trials and 13 line trials. In the no-training condition, subjects completed the SRRS with no practice. Although the training procedure required that participants complete a longer form, return rates were not affected by this variable: 27 subjects in each group returned correctly completed questionnaires.

The second factor was the dimension that subjects used in rating the SRRS events. In one condition, social readjustment, the instructions were identical to those used by Holmes and Rahe (1967), that is, a three-paragraph description of the meaning of social readjustment, how to do magnitude estimations, and three examples of proportionally matching numbers to events. However, in the second con-

dition, stressfulness, the words *social readjustment* were replaced with *stressfulness*, and the word *change* was replaced with *stress*. One of the examples in the original SRRS instruction set was omitted from the instructions for the stressfulness condition, as there was no satisfactory means for changing the example so that it concerned stress and not social readjustment. One sheet of each questionnaire requested demographic information such as age, sex, education, income, and occupation.

Results

The hypotheses that training and rating dimension affect event coefficients were tested by a 2 (training vs. no training) × 2 (rating dimension: readjustment vs. stress) × 42 (the SRRS events) unweighted means, repeated measures analysis of variance (ANOVA). Data based on magnitude estimation procedures have repeatedly been demonstrated to conform to a log normal distribution (Stevens, 1974); thus, to meet the normality assumptions of the ANOVA, base-10 logarithms of raw scores were submitted to the analysis. Since departures from homogeneity of the variance-covariance matrices in repeated-measures ANOVAs produce positively biased *F* ratios (Box, 1954), the obtained *F* ratios were tested assuming both the worst case of the variance-covariance violations and assuming the case with no violations at all. If *F* ratios are significant with degrees of freedom adjusted for the

Gaining a new family member	433	259	Vacation	189	117
Change in residence	296	158	Christmas	192	90
Child leaving home	403	226	Change to new school	215	141
Marital separation	1,219	443	Begin schooling	237	161

worst violation, then we have confidence in the effect. If an *F* ratio is not significant with this conservative test, yet is significant when tested under the no-violation condition, we are less confident in the effect and need more information to make any conclusive statements (Greenhouse & Geisser, 1959).

Table 1 presents the summary of the ANOVA with both uncorrected and conservative probabilities for each *F* ratio. The hypothesis that psychophysical training affects ratings of events was not confirmed, $F(1, 50) = 1.78$, *ns*. The significant main effect of rating dimension, $F(1, 50) = 12.15$, $p = .002$, confirms the hypothesis that ratings of

stressfulness were different from ratings of social readjustment. For all but three of the events rated, coefficients produced in the stressfulness condition were equal to or higher than the ratings of social readjustment. A significant main effect for events with a very high *F* ratio, $F(41, 2050) = 24.18$, $p < .001$, was expected. This simply indicates that different events were given different ratings. A significant Rating Dimension \times Events interaction was also observed, $F(41, 2050) = 1.58$, $p = .012$; but because the interaction is not significant under the conservative test, $F(1, 41) = 1.58$, $p = .215$, we are less confident in the effect. Geometric

Figure 1. Relationship between arithmetic and geometric means of Social Readjustment Rating Scale (SRRS) weightings and geometric means of stressfulness and social readjustment conditions.

means for each of the rating dimensions, averaged across the training factor, are presented in Table 2.

Event coefficients obtained in the social readjustment condition, collapsed over levels of the training factor, are similar in magnitude to the coefficients that Holmes and Rahe (1967) found for the SRRS. Figure 1 presents the coefficients of the social readjustment condition found by us and Holmes and Rahe, as well as those obtained in the stressfulness condition of the present study. The observed differences between Holmes and Rahe and the present study's coefficients obtained in the social readjustment condition are largely a function of the measure of central tendency used to represent the data (see Figure 1). Thus, the social readjustment condition of the present study replicates the data that Holmes and Rahe obtained.

Discussion

To our surprise, trained subjects did not produce coefficients significantly different from those produced by the nontrained subjects. Thus, it is plausible that subjects can do magnitude estimations with little training, though Stevens (1974) believes that some practice may be useful. At least one

other interpretation of this finding must, however, be noted—The magnitude-estimation training instructions may not have been effective. Some support for this hypothesis lies in our observation that several subjects apparently used a straightedge while completing the training. Since the instructions did not explicitly prohibit this, an oversight on our part, it is possible that this occurred frequently. If this was the case, we must conclude that the training hypothesis was not adequately tested.

Coefficients from the stressfulness condition were shown to deviate significantly from the coefficients in the social readjustment condition in both elevation and configuration over events. But what do these differences mean to the life events researcher? Scale differences must be evaluated in light of the original purpose of weighting the events with these ratings; namely, is illness contraction related to the experience of life events? In predicting various illnesses from measures of life events, a single life events score is usually computed as a weighted linear combination of the events experienced. The weights are determined by subjects' ratings of events along some semantic dimension. Therefore, different rating dimensions would be expected to alter the weights used in forming

the linear combination. Changing these weights is likely, in turn, to alter the correlation between the life events score and the criterion, particularly if the relationship between the weights from the two rating dimensions is *not* monotonic and linear. Given the obtained interaction between rating dimension and events, we expect that correlations between events and an illness criterion will vary depending on the dimension used.

Our data demonstrate that the set of weights that an investigator uses may be linked to the prediction of criterion scores. Unfortunately, the direction of this effect is unknown. The researcher is thus left in the unenviable position of choosing among scales. An obvious and somewhat tempting resolution of this dilemma is for the investigator to use *all* sets of coefficients and empirically, for example, using a multiple regression analysis, determine the best combinations of scales for the set of data. One must wonder, though, what is to be learned about the perception of life events and their relationship to the criterion from such an exercise. Stated differently, the meaning of the weights yielded by a multiple regression is not tied to any substantive dimension of the events, such as social readjustment or stressfulness. Because the meaning of the prediction is of basic importance, identification of the factors that subjects use to rate life events is necessary for the advancement of an understanding of the interaction of life events with illness and psychological functioning.

We suggest systematic investigation of the properties or dimensions that subjects incorporate in their ratings. Multidimensional scaling methods are available for both testing the validity of rationally constructed dimensions and for deriving dimensions with no preconceptions. Nelson (1967) has similarly suggested that multidimensional analyses, in particular discriminant and factor analysis, be used for evaluating life events. Explorations along these lines have the potential to greatly clarify the complex inter-

actions that exist between person and environment.

Mood, Pleasant Events, and Unpleasant Events: Two Pilot Studies

Lynn P. Rehm
University of Pittsburgh

The relationship between mood and both pleasant and unpleasant events is assessed in two studies. Undergraduates made self-ratings of mood and kept daily logs of pleasant and unpleasant events for approximately 2 weeks. Intrasubject correlations in both studies suggested that mood was related to pleasant and unpleasant events independently. Intersubject correlations were consistent but nonsignificant. Cross-lagged correlations were significantly less than same-day correlations. Weighted event scores produced marginally higher correlations with mood than unweighted scores. Minor sex differences are noted. The implications of these results for theory and practice are discussed.

A common assumption in the behavioral literature on depression is that mood is a function of reinforcement (e.g., Ferster, 1973; Lewinsohn, 1974). Although some basic questions relating to the precise definition of reinforcement in daily life remain unanswered, empirical relationships have been obtained between mood and pleasurable events or activities that have a likely correspondence to reinforcement. Using the Pleasant Events Schedule (MacPhillamy & Lewinsohn, Note 1), a 320-item list empirically developed to assess potentially reinforcing events in daily experience, intraindividual correlations have been demonstrated between mood and number of pleasant events (Lewinsohn & Graf, 1973; Lewinsohn & Libet, 1972). Depressed persons have been found to report fewer pleasant events than nondepressed psychiatric and normal groups (MacPhillamy & Lewinsohn, 1974). Wener and Rehm (1975) demonstrated a causal relationship between manipulated rate of positive feedback in a laboratory task and subsequent mood.

Self-monitoring of mood and pleasant events has been a part of a number of treatment programs for depression with a variety of rationales and functions. Lewinsohn's (1974) clinical research program employed the Pleasant Events Schedule as a means of empirically selecting targets for behavioral intervention. Events that correlate with mood for a specific individual are increased in order to influence mood (Lewinsohn, 1976). Fuchs and Rehm (1977) developed the Positive Activities Schedule, consisting of 20 categories of instrumental behavior likely to be associated with reinforcement. Depressed subjects kept a log of their daily activities using the schedule as a guide. Logs were used as a basis for self-selection of target behaviors and were also assumed to be an intervention in and of themselves, that is, an intervention modifying depressive, pessimistic self-monitoring.

Anton, Dunbar, and Friedman (1976) used activity logs as part of a therapy program that included scheduling of individual reinforcing activities. Enjoyability ratings of each activity logged were described as a potential dependent variable. Ad hoc activity schedules were used in three case studies described by Rush, Khatami, and Beck (1975). Activity data were used to confront clients' cognitively distorted interpretation of their behavior. Another ad hoc use of activity logs

^a *n* = 10.

^b *n* = 20.

was described by McLean (1976), who used them primarily to assess improvement in behavioral productivity as one alternative component of therapy for depression.

Given the widespread use of pleasant event or activity monitoring in depression therapy programs and the empirical support for the relationship between pleasant events and mood, it is somewhat surprising that only activities associated with reward have been studied. All of the research cited has dealt with "pleasant events" or "positive activities," yet aversive events have been related to depression in a number of ways. Aversive, stressful life events have been found to precede clinical depression (cf. Dohrenwend & Dohrenwend, 1974). Seligman (1975) has demonstrated empirically that noncontingent aversive events lead to a state of learned helplessness, which he associates with depression. Lewinsohn, Lobitz, and Wilson (1973) found that depressed persons were particularly sensitive to aversive events. It would seem logical that mood would be related to aversive events in the daily life of normal persons.

Two pilot studies were conducted to explore the feasibility of assessing the relationship between unpleasant events and mood in a manner that could be adapted to clinical usage. In both studies events were listed by individuals in positive or negative columns on a daily log with a general definition as a guide. Pleasant events were defined as any event that is pleasant, enjoyable, or rewarding, and unpleasant events were defined as any event that is unpleasant, aversive, or punishing. Mood was assessed on a daily basis on a 0-10 rating scale, anchored at 0 = worst

mood ever to 10 = best mood ever. This scale was adopted for simplicity and ease of administration. Aitken (1969; Aitken & Zealley, 1970) described the use of a similar simple scale that correlated well with psychiatric ratings of depression. In both studies subjects were instructed to make their mood ratings and then fill out the events logs daily at the end of the day.

Study 1

Method

Log sheets and standard instructions were given as a class assignment to 33 undergraduates enrolled in a psychology course. Usable data were obtained from 30 subjects (10 males and 20 females) who kept logs for approximately 2 weeks (1 for 13 days, 13 for 14 days, 15 for 15 days, and 1 for 16 days).

Results

The actual events recorded varied somewhat in specificity and type. Some sample pleasant events that were recorded by students included "read Sunday paper," "good lunch," "sunny day," "letter from Adrienne," "bought albums," "good grade on bio test," "Joni Mitchell concert," "party," "saw good movie," "got high," and "complimented by Mrs. F." Some examples of unpleasant events were "bio test," "dentist appointment," "got parking ticket," "missed bus," "got blister playing squash," "Pitt lost game," "argument with roommate," "did the laundry," and "dull Geography class."

Means for data collected are shown in Table 1. Males' ratings of their mood were significantly lower than those for females, $t(28) = 3.66$, $p < .01$. Differences in number

Pleasant and unpleasant events	-.15	-.28	-.22	—	—
Mood and events (<i>R</i>)	.75	.68	.70	—	—

^a *n* = 10.

^b *n* = 20.

^c *n* = 30.

of events were not significant though in directions consistent with the mood differences.

Mean correlations were calculated using Fisher's *z* transformation and were then converted back to Pearson product-moment correlations. No significant differences in correlations were found between sexes. Looking at the total group, the average correlations between pleasant and unpleasant events with mood were all statistically significant. The relatively low, negative, average correlation between the two classes of events suggests that pleasant and unpleasant events make relatively independent contributions to mood. The average multiple correlations for pleasant and unpleasant events correlated with mood (see Table 2) were larger than either single correlation and this further suggests mood is a function of both pleasant and unpleasant events.

Lewinsohn and Libet (1972) posed the question of whether mood would be affected by the previous day's activity or whether mood would affect the subsequent day's activity. This question can be answered by looking at correlations between mood and events of the previous day and between mood and events of the subsequent day. Table 2 shows that these mean cross-lagged correlations are quite low and comparable to those obtained by Lewinsohn and Libet. The same-day correlations were significantly larger than those for mood and events of the previous day: For mood and pleasant events, $t(29) = 9.30$, $p < .01$; for mood and unpleasant events, $t(29) = 5.40$, $p < .01$, or for those for mood

and events of the subsequent day, for mood and pleasant events, $t(29) = 6.55$, $p < .01$; for mood and unpleasant events, $t(29) = 5.95$, $p < .01$. Thus there was no indication of causality from events of one day to mood on the next or from the mood of one day to the events of the next. Lewinsohn and Libet's finding for pleasant events and mood was replicated and extended to unpleasant events as well.

Although the methodology is directed toward intrasubject questions, intersubject data can also be derived. For the 30 subjects, average mood correlated .31 with average pleasant events and $-.28$ with average unpleasant events. The multiple correlation between mood and both event scores was .57. These data are consistent with the intrasubject data, though only the latter correlation is statistically significant ($df = 28$, $p < .01$). A correlation of .46 ($df = 28$, $p < .05$) between average pleasant and average unpleasant events suggests individual differences in list length for this self-monitoring format.

Study 2

The second study had three purposes: (a) to replicate the first study with regard to monitoring pleasant events; (b) to determine whether a value weighting for each event would yield an obtained reinforcement measure that would enhance correlations with mood; and (c) to determine whether perceived contingency contributes to mood correlations.

Table 3

Average Mood and Events Data Across 14 Subjects: Study 2

Variable	Raw score		Weighted score		Contingent score	
	<i>M</i>	<i>SE</i>	<i>M</i>	<i>SE</i>	<i>M</i>	<i>SE</i>
Mean daily mood ratings	5.83	.80	—	—	—	—
Mean daily pleasant events	5.53	1.96	32.52	12.51	19.33	7.66
Mean daily unpleasant events	3.68	1.71	21.00	10.60	11.22	8.27

Method

Thirty-four undergraduates enrolled in a psychology course were assigned a choice of projects, one of which was to participate in this study. Fourteen students elected to participate and kept monitoring data for 14 days. Instructions were the same as in Study 1, except for the addition of weighting and perceived contingency instructions. After recording each event, subjects were instructed to give it a value on a 0-10 scale. For pleasant events, 10 was to signify "an extremely enjoyable or pleasant event," and for unpleasant events, 10 was to signify "an extremely aversive or unpleasant event." Zero signified neutrality on either scale.

To assess perceptions of contingency, participants were asked to indicate how many of the value points assigned to each event were directly attributable to themselves or their own behavior (i.e., their effort or lack of effort or their skills or lack of skill). This method allowed for a more continuous assessment of degree of perceived response contingency than would a dichotomous yes or no. Attribution research (cf. Weiner et al., 1971) suggests that such judgments are continuous.

Results

The average daily mood rating for these subjects was 5.83, which corresponds closely with Study 1. Subjects in this study (see Table 3) recorded more events, both pleasant, $t(42) = 2.652$, $p < .05$, and unpleasant $t(42)$

$= 2.050$, $p < .05$, than subjects in Study 1. These differences may be due to a different set acquired from the class discussion of the project or to self-selection differences. In either case they do not effect the hypotheses in question.

Mean correlations between mood and events (see Table 4) were slightly smaller but comparable to those obtained in Study 1. Again, pleasant and unpleasant events were uncorrelated with each other on the average, but each contributed to mood variance.

The use of weightings enhanced the average intraindividual correlations to a minor degree. A comparison of pairs of correlations with mood between unweighted and weighted pleasant events scores indicated that the weighted correlations were larger to a marginally significant degree, $t(13) = 1.809$, $p < .05$, one-tailed. The increase in the mean unpleasant events correlation with weighting was not significant, $t(13) = 1.240$. Thus the evidence suggests that weighting event scores may have only a slight value in identifying relationships with mood more accurately.

The average correlations of mood and self-attributed points were of the same magnitude as the correlations between mood and

Table 4

Average Intrasubject and Intersubject Correlations: Study 2

Correlated variables	Intrasubject <i>M</i>			Intersubject <i>M</i>		
	Raw scores	Weighted scores	Contingent scores	Raw scores	Weighted scores	Contingent scores
Mood and pleasant events	.51	.59	.52	.12	.18	.09
Mood and unpleasant events	-.35	-.41	-.27	-.13	-.12	-.13
Pleasant and unpleasant events	.08	-.01	.03	.71	.62	.50
Mood and events (<i>R</i>)	.70	.75	.70	.33	.34	.22

number of events. No particular advantage appears to accrue from specifying reinforcement value that is perceived as contingent on the person's own behavior.

Again it is notable that the average correlation between pleasant and unpleasant events was close to zero. Each class of events appears to contribute to mood independently. Average multiple correlations between mood and both sets of event scores (Table 4) bear out this assertion.

As can be seen in Table 4, interindividual correlations between mood and events were in the predicted directions but were quite small and not statistically significant. Correlations between pleasant and unpleasant events scores were significant for raw scores ($p < .01$) and weighted scores ($p < .05$). These suggest significant individual differences in reporting rates for pleasant and unpleasant events even though these classes are relatively independent within subjects. Multiple correlations for mood with the events scores combined were again consistent with intrasubject findings but were not statistically significant.

It is particularly interesting that perceived contingent event scores do not enhance correlations with mood. As an additional way of examining whether perceived contingency is related to mood, a ratio of self-attributed points to total weighted scores was calculated for each subject for both pleasant and unpleasant events. Averaged across all individuals, 59.4% of the value of pleasant events was self-attributed, whereas 49.5% of the value of unpleasant events was self-attributed. Correlations between these ratios and average mood would indicate whether subjects who tend to attribute a greater proportion of their pleasant or unpleasant events value to themselves would be more or less depressed than subjects who see these events as less contingent. The correlation between the ratio of perceived contingent pleasant events and mood was $-.14$. The correlation between the ratio of perceived contingent unpleasant events and mood was $.004$. Needless to say, neither was significant. Thus there was no evidence that tendency to perceive contingency between events and behavior influenced mood in this study.

Discussion

These two studies suggest that even with this simple methodology, it is feasible to assess the relationships between mood and events, both pleasant and unpleasant, in meaningful ways. Despite individual differences in recording rates, pleasant and unpleasant events were recorded with relative independence, and each correlated with mood. The magnitude of correlations between mood and pleasant events using these less structured methods was comparable to that obtained by Lewinsohn and Libet (1972) and Lewinsohn and Graf (1973). Although the correlations with unpleasant events were regularly of a lesser magnitude, they nevertheless make a significant additional contribution to mood.

Evidence from the second study suggests that a simple scaling of event magnitude contributes only marginally to greater precision in identifying relationships between mood and events. Differentiating the value by the degree to which events are self-attributed did not seem to contribute to correlations with mood for either pleasant or unpleasant events. Events are related to mood whether contingent on one's own behavior or entirely external in origin.

Thus there appears to be a potential clinical value to self-monitoring unpleasant as well as pleasant events in conjunction with behavior therapy for depression. Unpleasant events that correlate with mood may also be appropriate target activities for modification (Lewinsohn, 1976). The data generated by monitoring unpleasant events may also contribute to helping clients make more accurate discriminations about functional relationships between their behavior and their mood. As a result, they may be able to make more realistic evaluations and set more realistic goals via techniques analogous to those used by Fuchs and Rehm (1977) or Rush et al. (1975).

Certain qualifications must accompany these conclusions. First, these studies should indeed be considered as only promising pilot studies. Problems concerning the precise definition and validity of unpleasant events remain, as they remain for pleasant event re-

cording. Further basic research is certainly necessary. Second, these studies suggest potential for monitoring unpleasant events only in terms of intrasubject investigations. Inter-subject correlations were largely nonsignificant; individual differences in recording rates were evident; and sex differences were obtained. The development of structured methods for assessing unpleasant events, parallel to those available for assessing pleasant events, may allow for valid nomothetic studies.

Cognitive and Personality Factors in Suicidal Behavior

Andrew M. Geller
Yeshiva University

Alvin Atkins
Montefiore Hospital and Medical Center
New York, New York

The role of aggression in suicidal behavior is studied. The personality functioning of 20 suicide attempters, 20 nonsuicidal psychiatric controls, and 20 suicide completers was assessed using the Rorschach. There were 11 women and 9 men in each group, and their ages ranged from 21 to 63. Feffer's role-taking task provided a test of the cognitive functioning of the first two groups. All three groups experienced the breakthrough of more aggressive than libidinal drive derivatives, but no significant differences between the groups were found. Only the suicide attempters' aggressive responses were more primitive than their libidinal responses. On the role-taking task, the suicidal group's cognitive functioning in the neutral situation was superior to their functioning in the aggressive one. The control group yielded no such difference. The suicidal group's performance in the aggressive situation was also significantly inferior to the control group. These results are interpreted as underscoring the role of cognition in symptom choice.

Conflicts over aggression play a central role in the psychoanalytic theory of suicide. Freud (1917/1957) struggled with the problem of how the ego, with its self-love and narcissistic libido, could allow its self-destruction. The answer, he theorized, lies in the ego's treating itself as an object, directing against that object the hostility and sadism that were its original reaction to objects in the outside world. Freud (1920/1950) later added to his theory the concept of a drive toward death, to be found in the controlling, coercing, and punishing components of the superego. In depression, the superego obtains a hold on consciousness and, as a "pure culture of the death instinct," drives the ego into death.

Other psychoanalytic thinkers have modified this theory. Zilboorg (1937) wrote that suicide is likely only when the individual has identified with a dead person, and that the process of identification has to take place

during childhood or adolescence, at a time when the incorporated person is already dead. Menninger (1938) agreed with Freud that suicide is the wish to kill another turned inward, but he also saw it as the ego's punishing itself for that crime and wishing to be killed.

Although the early psychoanalytic literature on suicide was based primarily on case studies, later writers have attempted broader, more experimental analyses of the role of aggression in suicidal behavior. Their results are inconclusive. Several researchers found that suicidal individuals are more hostile than nonsuicidals (Vinoda, 1966), that their dreams contain more themes of violence than control subjects (Raphling, 1970), and that they tend to resent those on whom they depend (Lester, 1969). Others found no significant differences in aggressive impulses or ideation between suicidal and nonsuicidal subjects (Eisenthal, 1967; Fisher, 1971).

Little research has focused on the role of cognitive functioning in suicidal behavior, although there is evidence to suggest that cognitive dysfunction can lead to symptomatic behavior. Feffer (1959) extended Piaget's (1950) concept of decentering activity in the

This article is based on a doctoral dissertation submitted by Andrew M. Geller to Yeshiva University under the supervision of Alvin Atkins.

physical, inanimate world to an analysis of the individual's cognitive structuring of social content. In his theory, roles and role reciprocals are the social polarities in a relationship of subject and interpersonal object that parallel the subject-object relationship of impersonal cognition. In order for subjects to construct the reality of the other accurately, to be able to modulate their behavior in anticipation of the behavior of the other, they must be able to coordinate simultaneously their role and the role of the other in the same situation. They must be aware of both perspectives. Prior to attainment of this ability to simultaneously decenter in social situations, the subjects are able only to react to the behavior of the other. At yet a more primitive level, subjects have great difficulty even being aware of perspectives different from their own, and their behavior is almost exclusively egocentric.

Lowenherz and Feffer (1969) found that adult subjects had greater difficulty coordinating role perspectives when the role was one that was defensively isolated, that is, when the subject had defined one of the role reciprocals as "least like me" or "personally unacceptable to me." This elaboration of Feffer's model of interpersonal cognitive development has been used to explain symptomatic behavior. Such behavior may be thought of as the result of isolation between dynamically relevant schemata. The subjects' relationship to reality is distorted, as they focus on only one dimension in the situation, unaware of the corrective influence of the opposite perspective. For example, Ward (1976) tested the hypothesis that the "other" in psychotic delusions, particularly if that other is a malevolent, threatening figure, is a representation of defensively isolated aspects of the self. She found that the subjects indeed functioned at a more primitive cognitive level when taking the roles with delusional themes than they did when working with neutral themes.

The present study examined both cognitive and defensive functioning in seriously suicidal individuals. Given the central rule that aggression plays in the psychoanalytic theories of suicidal behavior, it was predicted that within the suicidal group there would be more break-

through of primary process elements in response to aggressive stimuli or impulses than in response to libidinal stimuli and impulses, and the defenses against these breakthroughs would be less effective for aggressive than for libidinal material. It was expected that as a result of these weak defenses, the thinking of the suicidal subjects would contain a greater proportion of primary process elements than would the thinking of the control group in dealing with aggressive stimuli and impulses. Finally, it was predicted that subjects whose symptomatic behavior included making serious suicide attempts would have difficulty coordinating the roles represented by that symptom, namely victim and aggressor. This difficulty has been interpreted as a function of the subject's more primitive cognitive functioning when assuming the role of the aggressor, which is the reciprocal of the symptomatically exaggerated role orientation of the victim.

Method

Subjects

There were two groups of subjects, one experimental and one control. Each group was comprised of 20 subjects with a wide range of age, education, and socioeconomic status. All subjects were inpatients in a private psychiatric hospital in New York City.

The first experimental group was made up of 20 randomly selected patients who had made serious suicidal attempts. Only subjects whose suicide attempts were potentially lethal were included in this group. Patients who met that criterion but at the time scheduled for testing were overtly psychotic (actively hallucinating and delusional) were excluded from the study. Also excluded were patients who were diagnosed as suffering from more than minimal brain damage, more than minimal retardation, or a life-threatening physical illness. Although each subject's diagnosis, at both admission and discharge, medication regimen, family history, sex, marital status, education, and socioeconomic level were noted, these factors played no part in determining eligibility for the study.

The control group, also comprised of 20 subjects, was made up of randomly selected inpatients at the same hospital. Each subject had no history of suicidal ideation, suicidal impulses, or gestures. Both the history of the subject's present illness and past history as recorded in the chart, plus consultation with the subject's therapist, were used in making this determination. As with the experimental group, patients who were actively psychotic or suf-

fering from serious organic brain disease, mental retardation, or a life-threatening physical illness were excluded.

A third "group" was composed of data from patients who had actually committed suicide. Twenty Rorschach protocols were randomly collected from records of subjects who were tested while inpatients at the hospital and who within 1 year of that testing killed themselves. The use in this study of the available data from this group is an attempt to partially eliminate a conceptual difficulty found in most research on suicide. In general, such studies have examined subjects who attempted suicide and maintained that the findings were also applicable to those individuals who succeed in killing themselves. In this study, the data from those who committed suicide were used as a comparison with the information obtained from the suicide attempter group, providing some notion of the validity of that information.

The demographic characteristics of all three groups were similar. The ages ranged from below 20 to over 60, with a majority of subjects between 20 and 50 years of age. There were 11 women and 9 men in each group, and all three groups were virtually all Caucasian with the exception of 2 black subjects. Over half of the subjects in each group were single. In the nonsuicidal group, over half were Catholic, but religion was fairly equally represented in the other groups. All subjects in each group were high school or college graduates.

Procedure

All testing was done in individual sessions held in an office on the subject's inpatient unit. Inclusion in the study was voluntary, and each subject was assured of confidentiality and anonymity.

There were two parts to the stimulus situation. The Rorschach was used to test the defensive functioning of the subjects in the presence of aggressive and nonaggressive stimulation. Feffer's (1959) role-taking task (RTT) was used to measure their cognitive functioning in aggressive and neutral situations. The two tests were presented to the subjects in counterbalanced order.

Rorschach

The Rorschach inkblots were administered to each subject in the usual fashion. Subjects were first shown the 10 cards in sequence and were asked to tell what they looked like or reminded them of. On the first two cards, if only one response was given, another was requested. Thereafter, no further encouragement was given by the examiner. After the subjects had responded to all 10 cards, they were asked to go through each one again with the examiner to explain what it was about the blot that determined the response given.

Subjects' responses to the Rorschach were scored according to Holt's (Note 1) system for scoring primary process on the Rorschach. For Holt, the

distinction between primary and secondary process is a function of the degree to which drive dominates logic and reality in a response and the nature of the drive itself. Holt's system measures manifestations of primary process on the Rorschach and the means by which a person tries to control it and defend against the anxiety its emergence presumably entails. Scorable Rorschach responses are divided into two groups, those motivated by libidinal drives and those resulting from aggressive drives. These two categories are further divided into 11 subgroups, such as oral, anal, aggression-subject, and aggression-object. Each response is scored 1 or 2 depending on its level of what Holt called "primariness." The arbitrary boundaries between the two levels are defined by two points. One is a continuum from raw, shocking, blatant, or primitive forms of the drive in question (Level 1) to civilized, socially acceptable forms that are more appropriate to social communication between strangers in a professional situation (Level 2). The second criterion is the degree to which the response focuses on the drive-relevant aspect of an image, a division useful primarily for libidinal responses.

Because this binary division seemed too crude, Holt introduced a 5-point scale of Defense Demand (DD), which serves primarily to further differentiate responses along a continuum of primariness, with the DD score rising from 1 to 5 as the response becomes less socially acceptable and more bizarre. The DD score is a function only of the underlying idea of the response. However, the way in which that idea is expressed is obviously also important in an assessment of primary process. Holt dealt with this by including 47 categories in which to score methods of control or defense manifested in the response. The effectiveness of these defenses is recorded by yet another score, Defense Effectiveness (DE). This rating is a combined measure of a response's form level and the affect accompanying it, with a positive DE score reflecting a well-defended response and a negative score indicating one that was poorly defended.

Role-Taking Task

The assigned content of the RTT revolved around two themes, "hurt" and "please." Hurt was chosen to stimulate stories containing both aggressor and victim, with the role reciprocals viewed as central to the choice of suicide as a symptom behavior. The control stimulus was please, a theme chosen for its relatively neutral quality with regard to social desirability and dynamic impact.

Each subject was shown a white 5 × 8 inch (12.5 × 20.5 cm) index card on which two identical stick figures, separated by the word HURT, were drawn. The subject was directed to use the card as a take-off point for making up a story about two people, one of whom hurts the other. When the initial story was completed, the subject was shown another card identical to the first, except that an arrow was

drawn under the figure on the left. This time the directions were to "make believe that you are one of the characters in the story, the figure on the left. Tell the same story that you told before, but retell it from the perspective of that person, as he or she would tell it." Following completion of this story, the subject was shown a third card identical to the others, except that the arrow was now under the figure on the right. Instructions for this card were the same as for the second card, except this time the subject was asked to take the role of the other character in the story.

The subject was then shown another three-card series, with the word PLEASE replacing the word HURT on otherwise identical cards, and was directed to go through the RTT procedure again, this time telling a story about two people, one of whom does something to please the other. Half of the subjects were presented with the please theme before the hurt theme.

The two sets of stories produced by each subject were then scored to determine the subject's decentering level for each of the two themes. The scores obtained for the please stories were taken as a baseline of the subject's ability to coordinate roles and their reciprocals in a relatively neutral situation. Scores for stories containing the roles of victim and aggressor were used to indicate the change in the subject's cognitive functioning when dealing with defensively isolated aspects of personality.

All stories were scored twice, in accordance with the RTT coordination method and the RTT differentiation method. Although both methods assess the subject's ability to take different role perspectives, they provide different measures of this ability. The RTT coordination method focuses on the degree and quality of coordination between the different perspectives. Increasingly higher scores are given to reflect superior ability to assume different roles and shift from one to the other while maintaining inner-role consistency and balance in the situation described. At one extreme are the categories for obvious inconsistency between the characters' viewpoints. At the other extreme, the subject manifests an ability to synthesize the two perspectives, with each character mindful of the external role orientation of the other.

The RRT differentiation method provides a measure of the subject's ability to differentiate and coordinate attributes of the "self" and "other" within a single retelling of the initial story. Each retelling provides a measure of decentering ability from the perspective of one given role. The subject's ability to decenter was thus measured in four different situations, as victim, as aggressor, as "pleaser," and as "pleased," or in other words, as the subject of dynamically isolated role attributes and as the subject of attributes not dynamically isolated. Low scores indicate little or no shifting of perspective from one character to the other, whereas higher scores reflect an increasingly sophisticated ability of one character to be taken as the object of an internalized state of the other.

Table 1

Comparisons Within Groups of Responses With Libidinal or Aggressive Content

** $p < .005$.

Reliability of Scoring

Protocols from the Rorschach and the RTT were scored by both the examiner and another scorer, a graduate student in clinical psychology. Neither scorer knew to which subject group the protocol being scored belonged. Interjudge reliability coefficients were obtained for scores of the Rorschach and the RTT. The overall interjudge correlation on the Rorschach scores was .83. The coefficients were higher for the RTT. For the coordination scores the reliability coefficient was .88, and it was .96 for the differentiation scores. For all-numerical scores on which the judges differed, the final score was the average of the original two.

Results

The results of this study fall into two groups, those that indicate the subjects' personality functioning as reflected in their Rorschach responses and those based on the RTT scores that describe their cognitive functioning in interpersonal situations. The analyses of the results of this study were done with nonparametric tests, as the results were not normally distributed and did not have equal variances.

Personality Functioning: Rorschach Results

Table 1 summarizes the within-group comparisons for all three subject groups. As predicted, the suicidal subjects, both attempters and completers, experienced breakthroughs of significantly more aggressive than libidinal drive material in responding to the Rorschach. The nonsuicidal control group also had a greater percentage of aggressive than libidinal drive-related responses. However, the level at which that difference is significant was lower for the control group than for either of the suicidal groups.

The aggressive responses of the suicide attempters were significantly more primitive than their libidinal responses as indicated by the differences in DD scores. Comparison of those scores for the nonsuicidal control group did not yield significant differences between their aggressive and libidinal responses. The degree to which their responses were rated as primitive or bizarre was not a function of the particular drive content of the responses, although this was the case for the suicide attempters.

The suicide completer group also showed no significant differences between the DD scores of their aggressive and libidinal responses. This was the one instance in which their results did not parallel those of the attempter group.

Contrary to the prediction, no significant differences were found between the DE scores of the libidinal and aggressive responses for both suicidal groups. It therefore appears that even the attempter group, which experienced

the breakthrough of a great deal of primitive aggressive drive material, defended against their aggressive responses as well as they did against their libidinal responses. The completer group also was equally effective in dealing with the aggressive and libidinal material in the records.

Comparisons between the three subject groups on each of the Rorschach measures studied were all nonsignificant. The suicidal groups did not seem to be dealing with more aggressive drive material than was the nonsuicidal group. In addition, the suicidal group's defenses against those impulses were not more primitive or less effective than were the defenses of the control group. Table 2 summarizes the between-group comparisons for the two suicidal groups, and Table 3 contains the results of comparisons between the suicidal and control groups.

Cognitive Functioning: RTT Results

The results of the RTT coordination scores fully support the hypothesis that suicidal subjects function at a more primitive cognitive level than nonsuicidal subjects when presented with aggressive stimuli. Table 4 summarizes the within-group comparisons of coordination scores. Suicidal subjects were clearly deficient in their ability to maintain a consistent theme while taking the roles of both aggressor and victim, when their performances were compared to their ability to coordinate perspectives in a neutral situation. Nonsuicidal subjects manifested no such difficulty when their perform-

^a Mann-Whitney U; all values are *ns*.

ances with the aggressive and neutral themes were compared.

Although the coordination scores of the suicidal subjects for the hurt situation were significantly lower than their scores in the please situation, it is important to note that both of the mean coordination scores of the nonsuicidal control group were lower than either of the suicidal groups. Possibly the control group's lower coordination scores were a manifestation of the effect that their different psychopathologies had on their cognitive performance in that interpersonal situation. Perhaps the suicidal subject, in dealing at an unconscious level with aggressive impulses, has overemphasized the role of benevolent or nurturing person. In any case, this difference between the groups requires that the coordination scores of each subject group in the aggressive situation be compared to their scores in the neutral situation in order to measure the effect of the aggressive stimulus on performance. The mean difference score of the suicidal group differed significantly from that of the control group, with the suicidal subjects generally performing at a higher level in the neutral situation and the nonsuicidal subjects doing better in the aggressive situation. The mean difference between hurt and please for the suicidal and nonsuicidal groups was 2.55 and 1.45 respectively ($U = 132$, $p = .05$).

The results of the analyses of the differentiation scores of the two subject groups also support the hypotheses. The cognitive functioning of the suicidal subjects when taking the isolated role of aggressor was significantly more primitive than their performance in the ego-syntonic role of victim. There were no significant differences in their abilities to assume the role reciprocals with a neutral theme or in the nonsuicidal subjects' performances in any of the four roles. Interestingly, the suicidal subjects achieved their lowest differentiation scores among all roles when taking the role of aggressor and the highest of all their differentiation scores for the role of victim. These results are displayed in Table 5.

Comparisons between the two groups for the differentiation scores, found in Table 6, also support the prediction. The magnitude of the difference between the suicidal group's scores in the roles of aggressor and victim was significantly greater than the magnitude of the difference between the control group's scores for those roles. There were no such findings in the between-group comparison for the neutral situations.

Discussion

This study examined two major areas of functioning, cognitive and defensive. The results fully supported the hypotheses about

Table 4

cognitive functioning. The suicidal subjects differed from the control group in a very defined manner. When asked to take the reciprocal roles of aggressor and victim in a story about one person hurting another, a situation that highlighted what is presumably the central conflict in suicidal behavior, these subjects had difficulty in coordinating the same thematic material from two opposite perspectives. In addition, they were more adept at assuming the ego-syntonic role of victim than the ego-alien role of aggressor, with several of the suicidal subjects actually commenting that they "just couldn't" tell the story from the aggressor's point of view. These same subjects performed significantly better on all measures when taking roles in the dynamically neutral situation of one person pleasing another. They had less difficulty coordinating the two roles and took the roles of both

pleaser and pleased with equal facility. For the nonsuicidal subjects, there were no significant differences in their performance in either the aggressive or neutral situation, and their scores in the aggressive situation were significantly higher than those of the suicidal group.

The results of this study that pertain to defensive functioning partially supported the hypotheses. As predicted, suicidal subjects experienced breakthroughs into consciousness of more aggressive drive-related than libidinal drive-related material. Subjects who later committed suicide also seemed to have been dealing with more aggressive impulses during testing. In addition, the aggressive responses of subjects who had attempted suicide were more primitive and more bizarre than their libidinal responses.

Some of the results did not turn out as predicted. Although, as noted above, the aggressive responses of the suicide attempters were more primitive than their libidinal responses, there were no significant differences in the suicidal subjects' ability to defend against either type of response. There would seem to be at least two explanations for this. It may be that Holt's DE score, used in this study as a measure of the sophistication of a subject's defensive functioning, was not the most appropriate instrument for the task. That is, individuals may defend against bizarre or primitive responses in ways that are more or less immature or pathological. However, if the defense mechanisms, regardless of their sophistication, succeed in protecting the subjects from conscious anxiety or confusion, then they have been effective and would be scored as

Table 6

such. So, in interpreting these findings, it could be said of suicidal individuals that though in aggressive situations they may indeed use defenses that are developmentally immature, they do not necessarily decompensate in such cases to any greater degree than in other circumstances. Indeed, nowhere in the literature is it suggested that a clear sign of high suicide potential is a person's overt disorganization in response to aggression. Rather, the response is said to be an unconscious regression of the ego to more primitive forms of defense.

There is another explanation for the lack of significant differences between the libidinal and aggressive DE scores of the suicidal subjects. It is possible that there actually was no difference in the maturity of these subjects' defensive responses to the breakthrough of various types of drive-related material. Their ego functioning was not clearly defined under a variety of different circumstances, instead it remained fairly constant throughout. Such an interpretation can be expanded to deal with the other two findings in this study that were not predicted by the hypotheses.

It has been expected that significant differences between suicidal and nonsuicidal subjects would appear in their personality functioning in aggressive situations. This was not the case. There were no significant differences between the three groups on any of the Rorschach scores. Furthermore, just as with the two suicidal groups, the nonsuicidal psychiatric controls also experienced the breakthrough into consciousness of more aggressive than libidinal material on the Rorschach, although the degree of difference was not nearly as high for the control group. These results may be used to bring into question the psychoanalytic theory of the significance of aggression in suicide.

However, the similarity between the suicidal and nonsuicidal psychiatric groups can also be understood as a reflection of the importance of aggressive conflicts not only in self-destructive behavior but also in a number of other diagnostic entities. Jacobson (1971), in attempting to combine ego psychology with psychoanalytic drive theory, implicated aggression as a major factor in all

depression, whether suicidal ideation is present or not. Silverman (1966), using the technique of subliminal stimulation, showed that unconscious aggressive impulses are directly related to ego pathology in schizophrenia.

One therefore might well view various forms of psychopathology not as discrete entities but as forming a continuum of symptomatic expressions of universal conflicts. Both suicidal and nonsuicidal psychiatric subjects must deal with a large amount of aggressive drive-related material, because aggressive conflicts are a major factor in pathological ego functioning. Perhaps the overall severity of the pathology, whatever its form, is a function of the extent to which drive-related material breaks into consciousness.

This is not to imply that any such breakthrough is pathological. It is clear that aggressive impulses are an important component of the healthiest personality. The presence of these impulses can be seen as evidence of ego dysfunction only when it leads to severe anxiety or when aggression dominates the personality to the exclusion of other drives. Therefore, if so-called normal control subjects were tested and compared with suicidal or other hospitalized subjects, differences might be found in the percentages of aggressive responses in the total record or in the predominance of aggressive over libidinal material. But one could not expect to find such differences when dealing exclusively with a hospitalized population.

For the same reason, no significant differences were found either within or between groups for DE scores. As discussed above, these scores can be understood as measures of the individual's overall ego functioning, and none of the three groups functioned significantly more poorly than any other.

If aggression plays a major role in both schizophrenia and depression, whether suicidal ideation is present or not, what dictates the form in which the pathology will manifest itself? What determines the various symptomatic expressions of general ego dysfunction?

The results of this study suggest that the individual's cognitive functioning, the area in which the clearest differences between the suicidal and nonsuicidal groups were found, may

define the environment and thus determine the nature of symptom expression. Suicidal subjects do not differ significantly from their nonsuicidal psychiatric counterparts in overall level of ego pathology or overall level of cognitive functioning. However, they do show more markedly primitive functioning in interpersonal situations with aggressive content. In this area there is evidence of clear isolation among suicidal subjects between the role reciprocals of aggressor and victim. They are at their best cognitively when taking the role of victim, but they have so dissociated themselves from the ego-alien role of aggressor that perspective in the aggressive situation remains relatively unavailable to them.

One could say that they have thus defined their environment as one that precludes the direct outward expression of aggression, a relatively stable condition that in itself might not give rise to pathological behavior. However, when external events lead to the conscious experience of aggressive drive derivatives, the suicidal subjects can deal with the resulting breakdown of ego defenses only by treating themselves as victims. At deeper levels of the unconscious, such actions may indeed succeed in killing introjected others, but consciously the suicidal subjects can perceive the situation only as one in which they alone have been hurt. Because nonsuicidal subjects are able to assume the role of aggressor in an aggressive situation, self-destructive behavior is a less likely, and certainly a less necessary, outcome of the breakthrough of aggressive drive derivatives, though it may lead them to ego pathology as serious as that of the suicidal group.

The present study investigated relationships between the Kaufman Wechsler Intelligence Scale for Children-Revised factors (Verbal Comprehension, Perceptual Organization, and Freedom from Distractability), Wide-Range Achievement Test (WRAT) scores, and visual-motor maturation in a sample of 106 children. These children ranged in age from 6 to 13, and they had been referred for clinical evaluation because of a variety of school-related problems, including learning and classroom behavior problems. Results indicated significant correlations between the Verbal Comprehension factor and the Reading, Spelling, and Arithmetic measures on the WRAT and all measures of visual-motor maturation. The Perceptual Organization factor correlated significantly with Reading, Spelling, and all visual-motor maturation measures. The Freedom from Distractability factor correlated significantly with Arithmetic.

Since Luty (1967) and Sattler (1974) devised methods for the clinical use of Cohen's (1959) factor analysis of the Wechsler Intelligence Scale for Children (WISC), clinicians have increasingly used a factor score approach of WISC interpretation. No doubt this tradition will continue with Kaufman's (1975) factor analysis of the Wechsler Intelligence Scale for Children-Revised (WISC-R); and, in fact, Sattler has suggested WISC-R interpretations. Given this increasing trend toward use of the factor approach in clinical interpretation, it would seem important to establish correlational networks between WISC-R factor scores and other criteria, par-

ticularly those tests most commonly used by clinicians.

The present study sought to investigate relationships between the Kaufman factors Verbal Comprehension (VC), Perceptual Organization (PO), and Freedom from Distractability (FD); achievement, as reflected on the Wide-Range Achievement Test (WRAT; Jastak & Jastak, 1965); and perceptual maturation, as reflected in the Koppitz (1964) scoring of the Bender-Gestalt in a sample of school children referred for psychological evaluation. The following relationships were hypothesized: (a) Since the VC and PO factors, as identified by Kaufman, are equivalent to the Verbal and Performance IQ scores on the WISC-R, a positive relationship with Reading and Spelling on the WRAT was anticipated. (b) Since Verbal IQ has been shown to be positively related to WRAT Math scores (Jastak & Jastak, 1965) and since math is thought to be sensitive to dis-

Method

Subjects

The subjects for this study were students (76 males and 30 females). These students ranged in age from 6 to 13 with a mean age of 9.5 and were distributed across grade levels as follows: first, 13.2%; second, 16.9%; third, 17.9%; fourth, 11.3%; fifth, 10.4%; sixth, 14.1%; seventh, 7.5%; and eighth, 8.4%. Their IQs ranged from 60 to 118 with a mean of 88.1 and a standard deviation of 13.1. All were referred for evaluation because of learning and/or classroom behavior problems. Of these 106 subjects, 90% had a Spanish surname, and it is likely that a high percentage of these subjects are bilingual. The remainder were Anglo or black, with blacks constituting only 2% of the total sample.

Procedure

As part of a service contract with the parochial school system, Archdiocese of San Antonio, WISC-R, WRAT, and Bender protocols were collected during the 1975-1976 school year. Because of a desire to study factor structure per se, the WISC-R protocols were intercorrelated with respect to the 11 subtests, resulting in an 11 × 11 matrix. (The Maze subtest was not administered.) A principal-components analysis (with squared multiple correlations in the diagonal) was performed, terminating with an eigenvalue less than 1. Three factors, accounting for 64.6% of the variance, were retained and rotated according to the varimax criteria. Factor scores were computed for each subject, and these scores were transformed into normal distribution.

These factor scores, which were essentially equivalent to the Kaufman factors, were then correlated with age-appropriate WRAT Level 1 or Level 2 standard scores for Reading, Spelling, and Arithmetic and Koppitz error scores for the Bender-Gestalt protocols. Because Koppitz raw scores are more normally distributed in the 6- to 10-year-old age range, correlations were calculated only with subjects up through the fifth grade ($n = 77$). These error scores included total number of scorable errors, total significant, and total highly significant errors. Significant and highly significant errors are those that Koppitz (1964) found to occur in protocols of children diagnosed as brain injured.

Results

Table 1 presents the intercorrelation matrix for the 11 subtests, and Table 2 presents the factor structure obtained by the methods described above.

Table 3 presents Pearson correlations between the three factor scores and the WRAT standard scores for Reading, Spelling, and Arithmetic. As anticipated, the VC factor contributed significantly to Reading scores ($p < .005$), but it should be noted that the PO factor also was significantly related ($p < .05$), although the magnitude of the relationship was considerably less. The VC factor also was significantly related ($p < .005$) to Spelling scores, and again the PO factor made a small but significant contribution ($p < .05$). The FD factor, as expected, related significantly ($p < .005$) to the Arithmetic score and, as anticipated, the VC factor also contributed ($p < .05$). The PO factor apparently contributes little to Arithmetic as measured by the WRAT.

Table 4 gives Pearson correlations between the three factor scores and the total Koppitz Bender errors, the total significant errors, and the total highly significant errors. As predicted, there was a significant relationship, expressed negatively, between the PO factor and absolute and highly significant Koppitz Bender scores ($p < .05$ to $p < .005$). Of note are the significant ($p < .01$ to $p < .005$) associations of the VC factor with all Koppitz scores and the significant ($p < .01$ to $p < .005$) associations of the FD factor with both the absolute and significant Koppitz scores.

Discussion

The present study confirms that the Kaufman factors are related in clinically expected ways to WRAT achievement scores and visual-motor maturation scores in a sample of children referred for psychological evaluation. This finding is perhaps reassuring to

* $p < .05$.

** $p < .005$.

clinicians who, all too often, see Bender protocols that do not seem to fit at all with findings on the PO factor and distracted, anxious children with good Arithmetic and Digit Span scores.

Other relationships are also of interest. The PO factor's small but significant contribution to Reading and Spelling indicates that nonverbal intellectual factors make their contribution to those skills, as well as to Arithmetic. Also, both the VC factor and the FD factor were significant, suggesting that verbal mediators and attention factors are involved in visual-motor maturation processes.

Table 4
Correlations Between WISC-R Factors and Koppitz Bender-Gestalt Errors

Factor	No.	Total errors	
		Significant	Highly significant
VC	-.43***	-.27**	-.41***
PO	-.30***	-.15	-.22*
FD	-.28**	-.44***	.08

Note. WISC-R = Wechsler Intelligence Scale for Children-Revised; VC = Verbal Comprehension; PO = Perceptual Organization; FD = Freedom from Distractibility.

* $p < .05$.

** $p < .01$.

*** $p < .005$.

Perhaps, all of these additional relationships are not surprising, but they do suggest areas for further research regarding relative WISC-R factor contributions to related achievement and visual-motor maturation measures.

Finally, it should be noted that these data suggest that perhaps the factor structure for bilingual Mexican Americans is approximately equivalent to that of English-speaking subjects. Although this conclusion cannot be stated definitely due to the mixed nature of the sample, the evidence seems to point in that direction. Further research is also needed to ascertain whether bilingual factor structures are indeed equivalent.

INSTRUCTIONS TO AUTHORS

Style of manuscripts. Manuscripts must be prepared in the style described in the *Publication Manual of the American Psychological Association* (2nd ed.). Instruction on tables, figures, references, metrics, and typing (all copy must be double-spaced) appear in the Manual. Authors should submit manuscripts in triplicate and should keep a copy to guard against loss.

Abstracts. Manuscripts of regular articles must be accompanied by an abstract of 100-175 words. Manuscripts of brief reports must be accompanied by an abstract of 75-100 words. All abstracts must be typed on a separate sheet of paper.

Brief Reports. The *Journal of Consulting and Clinical Psychology* will accept Brief Reports of search studies in clinical psychology. The procedure is intended to permit the publication of soundly designed studies of specialized interest or limited importance which cannot now be accepted as regular articles because of lack of space. Several pages in each issue will be devoted to Brief Reports, published in the order of their receipt without respect to the dates of receipt of the regular articles. Most Brief Reports appear in the first or second issue to go to press following their final acceptance.

An author who wishes to submit a Brief Report:

1. Sends the Brief Report, limited to two printed pages and prepared according to the specifications given below.

2. Agrees not to submit the full report to another journal of general circulation.

Specifications. The Brief Report should give a clear, condensed summary of the procedure of the study and as full an account of the results as space permits.

To ensure that a brief report does not exceed two printed pages, follow these instructions for typing: (a) Set typewriter to a 48-space line. (b) Type text. (c) Count all lines except abstracts, title, and by-line, including acknowledgments. If you have exceeded 185 lines, shorten the material. (d) If your brief report barely exceeds 75 lines (one printed page), try to edit to 75 lines exactly. Reports slightly exceeding one page will be edited for length in order to use space economically.

In Brief Reports, headings, tables, and references are avoided or, if essential, must be counted in the 75 lines. This journal no longer requires an extended report, but, if one is available, each Brief Report must be accompanied by the following footnote:

Requests for reprints and for an extended report of this study should be sent to John Doe (give the author's full name and address).
The footnote should be typed on a separate sheet and not counted in the 75-line quota.

Freedom of Choice and Behavioral Change

Frederick H. Kanfer and Laurence G. Grimm
University of Illinois

A 3×2 (Treatment \times Population) factorial design with repeated measures (pretest/posttest) was used to evaluate the effects of perceived freedom of choice on behavior change in a therapy analogue study. Ninety subjects were assigned to three groups that varied in the amount of perceived choice given to subjects in determining the type of training procedure used for speed-reading enhancement. Experimental conditions were crossed with two populations of subjects to examine two levels of perceived freedom. Half of the subjects were drawn from a pool of psychology students required to participate in psychology experiments, and the remaining half of the subjects were volunteers. The main dependent variable was the amount of change in reading rate. A marginally significant ($p = .06$) increase in reading speed was obtained by volunteer subjects in comparison to subject pool participants. Subjects who perceived that they were given a choice in training procedures improved significantly more ($p < .02$) in reading speed than subjects who lost the freedom of choice. No changes in reading comprehension were noted. These findings are discussed in terms of the relationship between freedom of choice and performance in a behavior change program.

Increased sophistication about psychological treatment, a social trend toward self-help therapies, and the declining doctrine of the infallibility of mental health professionals have resulted in greater consumer selectivity among therapy agents and methods. With greater client understanding of behavior change methods, the client's acceptance of a treatment program has become even more critical for therapeutic improvement than before. It has long been established that motivation to change is essential for treatment success. Clinical folklore and current psychological theories suggest ample reasons for enhancing a client's belief that the treatment is voluntary and that he or she has some voice in deciding among treatment ap-

proaches in order to further cooperation. In fact, in many cases, especially when referred by agencies or other persons, the development of a motivation to change becomes a first treatment objective (Kanfer, 1975).

Laboratory findings closely match clinical experience. Liem (1975) found that students who were given a choice in selecting among different types of classroom sections did significantly better on exams and reported greater satisfaction with their sections and class leaders in comparison to no-choice subjects. Similarly, residents in a home for the aged who were given greater personal responsibility and choice in their daily routines showed significant improvement in alertness, active participation, and self-rated well-being than control subjects (Langer & Rodin, 1976). The belief that one has a choice also appears related to perception of increased control over an outcome. For example, choice of the order of taking a number of tests can reduce anxiety (Stotland & Blumenthal, 1964). The presence of an escape response from an aversive noise decreased the aversiveness of the threatening stimulus (Corah &

This study was supported in part by a grant from the University of Illinois Research Board.

The authors wish to thank Donald L. Barth and Robert Cherney for serving as experimenters.

Requests for reprints should be sent to F. H. Kanfer, Psychological Clinic, University of Illinois, 505 East Green Street, Champaign, Illinois 61820.

Boffa, 1970). Thus, a belief in personal control strongly influences the tolerance of aversive events (Averill, 1973; Kanfer & Seidner, 1973; Langer, Janis, & Wolfer, 1975). Langer (1975) found that choice in a chance situation increased confidence and risk taking. The freedom to choose among alternatives is thus related to perception of personal control.

The clinical implications of attributing a behavior change to one's own actions lie in the findings of better maintenance of that behavior (Davison & Valins, 1969; Kopel & Arkowitz, 1975). The finding of the facilitating effects of freedom of choice is supplemented by the finding that elimination of freedom or a threat to eliminate freedom has the opposite effects in activating the person to oppose such restrictions (Brehm, 1966). For example, a study by Brehm and Brehm (see Brehm, 1966) showed that subjects resisted persuasion when an authority figure acted in a dictatorial manner (i.e., "You must agree.") When the communication was phrased so as to not pose a threat to freedom, it was highly persuasive. Experiments on the effect of reactance suggest that a threat to eliminate freedom or an intentional deprivation of freedom yields detrimental behavioral changes with regard to an assigned task. The clinical parallel would be the referral of a client for therapy under conditions of coercion. Reactance and countercontrol (Davison, 1973) would be expected to interfere with the treatment process.

The forced referral to the therapist is somewhat paralleled in the experimental situation in which students in psychology courses are required to participate in research. Both the ethical and technical problems of using such subjects have been repeatedly discussed (Kelman, 1972; Schultz, 1969). Cox and Sippelle (1971) demonstrated that "true volunteers" markedly differed from nonvolunteers in mean heart rate changes over trials during an operant verbal conditioning procedure. In a recent study, Gordon (1976) examined the behavior of volunteer and nonvolunteer subjects who could either choose or were assigned to different relaxation treatments. Gordon found that volunteers valued the treatment more and reported it to be significantly more effective than subjects who had no

choice. These findings are also consistent with the work presented by Rosenthal and Rosnow (1975) that emphasized that the use of volunteer versus nonvolunteer subjects introduces important sources of bias in the experimental results.

The present study used a laboratory analogue to examine two critical problems in clinical practice: the client's freedom of choice in deciding to submit to therapy and the client's perceived choice in selecting among therapeutic procedures. A free-choice condition in selecting training procedures was used as an analogue to treatments that emphasize negotiation in establishing change programs. A lost-choice condition represented a situation in which a client enters therapy with expectations for negotiation but is then given the treatment that the therapist recommends. The analogue for this group is somewhat weaker, since in this study the experimenter also manipulated the prior expectations. A no-choice condition corresponded to the client who has no strong expectations about participating in deciding on treatment plans and does not choose a treatment. To increase similarity to clinical procedures, skill in reading was chosen as an area in which college students frequently experience problems. Specifically, this study examined the effect of (a) volunteer versus nonvolunteer participation and (b) choice versus imposition in selection of training procedures on improvement in brief speed-reading practice.

Method

Subjects

The subjects were 90 students at the University of Illinois at Urbana-Champaign. Forty-five subjects (23 males and 22 females) were enrolled in introductory psychology courses in which research participation credit was given toward their course grades. Subjects were required to submit their names for participation and were then assigned by computer to five experiments. The subjects had no choice in this assignment, but they could refuse to participate in a given experiment. The remaining 45 subjects (27 males and 18 females) were volunteers who answered campuswide advertisements that read "Wanted: Participants for a study concerning increased reading speed and comprehension." The nonvolunteers were assigned to a room and were scheduled for experimental participation by routine psychology department procedures. Volunteers con-

tacted the experimenter by telephone to arrange their appointments. Neither the advertising nor initial contact included an explicit or implicit statement about the subjects' opportunity to obtain remedial training. All subjects were randomly assigned to one of three groups in a 3×2 factorial design. Test and questionnaire data indicated that all groups were equivalent in pretest reading speed and comprehension, expectations for change, prior training experience, and motivation to learn speed reading.

Procedure

Subjects were seen individually and were told that the aim of the study was to examine the immediate effects of several different training techniques on reading rate and on comprehension. The long-term purpose of the experiment was said to assist in the development of reading skill programs. All subjects filled out a questionnaire to assess their interest in improving reading skills while the experimenter was seated behind them. After completion of the questionnaire, the subjects were given instructions for the pretest. The pretest consisted of a narrative passage at the low college level used by the University Counseling Center for establishing reading ability. The selected passages were from the book *Toward Better Reading Skills*. The subjects were told to read the passage quickly but to try also to understand the material, since they would be asked questions afterwards. When individual subjects indicated their readiness, the experimenter started a stopwatch and signaled them to begin reading. The amount of time taken to complete the reading of the standard passage was used as a reading speed measure.

After subjects had finished the reading task, they were given a comprehension test, comprised of multiple-choice questions. Following the administration of the comprehension test, subjects were seated in front of a small screen, which was used for reading skill training. Other training materials included a Carousel projector, set up for rear projection, and 50 slides of phrases ranging from 4 to 5 words each. The phrases were taken from a film strip produced by the Society for Visual Education, Inc., Chicago, Illinois, designed to improve reading skills. Each phrase was set up tachistoscopically so that it appeared on the screen for approximately .14 sec. Timers provided an interval of 5 sec between slide presentations. Immediately prior to the presentation of training materials, the subjects were told:

This study is examining training techniques and their effect on reading rate and comprehension. With the techniques that I will describe to you in a moment, it has been shown that even in one training session some improvement is possible. In the long run the techniques are all equally effective, but, due to individual differences, the method the person feels most comfortable with will probably be the most effective because it best fits his/her style of learning.

The remainder of the instructions were varied according to the group to which the subject was assigned. Subjects in the free-choice conditions were told: "We have found that almost everyone prefers to choose the techniques they work with. How about you? Would you also prefer to have a choice of which reading technique to use?" Subjects in the lost-choice group were given the identical instructions. For no-choice subjects the preceding instructions were omitted. All subjects, with the exception of one male and one female, indicated that they would like to have a choice. Since they did not wish to make a choice, these two subjects were excluded from further participation in the study.

Following these instructions, three training techniques were described to subjects in the following manner:

The first technique that can be used in training is a derivation of the Flourens-Derjeu ocular scan method. Although it has been shown to induce some eye strain in the learner, it is learned quickly and offers rapid improvement. The second technique is called the Mueller peripheral scope method. This method has been shown to produce a small amount of eye strain, takes longer to learn, and results in slower improvement. The third technique is the Morgan lateral field method. It involves a moderate amount of eye strain and requires a medium length of time to learn but yields a moderate and immediate improvement in reading.

Following the characterization of the training techniques, the free-choice group was asked, "Now that you have heard the description of the characteristics of each technique, which one would you prefer to work with?" After these subjects made their choice, the experimenter said, "OK, that's fine, we'll use that one." The lost-choice group was asked, "Now that you have heard a description of the characteristics of each technique, which one would you prefer to work with?" After these subjects had stated a preference, the experimenter went to the back of the laboratory, turned on the equipment, returned, and said, "I am sorry but I cannot give you that one, I will have to give you the _____ method." No-choice subjects were told that although these were the three methods generally used in research of this type, this experiment only used the _____ method. In spite of the fact that specific methods were identified, all subjects were exposed to an identical procedure. Prior to the presentation of the slides, all subjects were told:

You will be shown a slide for a fraction of a second, then there will be a brief rest, followed by another slide. The sequence will continue until all slides have been shown. Now, each slide will have a group of words on it. Try to take in the entire line in one look instead of reading across the line from left to right. I will let you know when all the slides have been shown.

The experimenter then went behind a partition and began to show the slides. After all 50 slides had been presented, the experimenter returned and asked the subject to move to the testing table. A second reading and comprehension test, matched for reading difficulty to the pretraining material, was then administered. This administration followed the same procedures outlined for the pretraining test. It should be noted, however, that in the presentation of the pretests and posttests, the passage contents were alternated to control for an order effect. Following the reading of posttest materials, a comprehension test was again given. All subjects were then told that it would require considerable practice over a period of weeks to actually improve their reading skills. However, the experimenter offered to give them the results of their reading tests as well as those of the study and to discuss with them any desire to take a remedial reading course. The subjects were then to fill out an "experimenter evaluation form." The evaluation form contained seven questions, rated from strongly agree (1) to strongly disagree (5). The items contained statements about the experimenter's manner, his competency, and his presentation of the material. After completion of the experimenter evaluation form, subjects were asked to deposit the form in the second author's mailbox on a different floor in the same building, immediately after the experiment. Those subjects who requested information about improving their reading skills were given prepared materials referring them to the University Counseling Center where such classes are offered.

Overall Design

The experiment consisted of a factorial design with two subject classifications (volunteers and nonvolunteers) and three treatment classifications (free choice, lost choice, and no choice). For all subjects, pretraining and posttraining scores were obtained for reading speed and comprehension. In addition, the pretraining motivation questionnaire and the posttraining experimenter evaluation questionnaire provided data to ascertain initial level of motivation for improving reading skills and postexperimental reactions to the experiment and the experimenter (as a test of potential reactance).

Results and Discussion

The main measure of the effects of the volunteer and choice variables was the change in reading rates following the 50-item training presentation. Table 1 presents the reading rates of all groups on the prereading and postreading tests and mean change scores. To assess the initial reading rate for all groups, a one-way analysis of variance on pretraining reading scores was performed. The nonsignificant $F(5, 84)$ of 1.67 indicates that the groups did not differ prior to the training sessions.

Note. Significant comparisons at $p < .05$ were obtained for pairs of groups identified by the same subscript. Reading rate was measured in words per minute.

To evaluate the relative change in reading rates among groups, a two-way analysis of variance (Groups \times Populations) was performed on raw change scores in reading rates from the pretest to posttest (Overall & Woodward, 1975, 1976). The main effect for the choice conditions was significant, $F(2, 84) = 3.13$, $p < .05$. A marginally significant main effect was obtained for the volunteer versus nonvolunteer comparison, $F(1, 84) = 3.38$, $p = .06$. Volunteer subjects showed a greater increase in reading rate in comparison to subjects drawn from the introductory psychology subject pool. No significant interaction effect was obtained.

The direction of the significant effect of choice conditions is indicated by the array of mean change scores. Subjects in the free-choice condition showed the greatest change, followed by the no-choice and lost-choice subjects. A Scheffé test was performed to locate the sources of the differences demonstrated by the significant main effect. The free-choice groups showed a significantly greater increase in reading rate relative to the lost-choice groups ($p < .02$). These results indicate that the opportunity to choose among alternative training techniques significantly affected performance as a result of the training session.

A two-way analysis of variance (Groups \times Population) on raw gain scores was used to assess changes in reading comprehension scores. The results indicated that neither volunteering nor choice conditions significantly affected reading comprehension changes. Reading rate and comprehension change scores were then transformed to residual change scores and were intercorrelated (Tucker, Damarin, & Messick, 1966). The correlation coefficient was nonsignificant ($r_{xy} = .06$). These findings indicate that changes in reading rates occurred independently of comprehension, and thus faster reading did not lower comprehension.

Since both male and female subjects and two experimenters participated, a two-way analysis of variance was used to test for the effects due to the experimenters as well as for sex. Neither analysis yielded a significant result.

The overall results are consistent with findings in other studies that subjects who perceived that they had a choice among alternatives performed more effectively than subjects who lost such a choice. The implications of these findings for clinical procedures are clear. Treatments that emphasize negotiation about therapy objectives and use participation of the client in the treatment process (Kanfer, 1975) would be expected to work more efficiently toward the therapeutic goals than clients on whom these goals are imposed or for whom the parameters of a procedure are not discussed. Champlin and Karoly (1975) have reported a preliminary investigation in which clients who participated in negotiating contract objectives showed significantly greater activity in the change program than those on whom contract conditions were imposed.

The present data do not permit a clear inference as to whether this difference was due to reactance (i.e., a decline in reading rate) in the lost-choice subjects or an enhancement (a positive motivational effect) in the free-choice group. Failure to obtain statistical differences between the no-choice group and the lost-choice group by the Scheffé test permits no firm conclusion in this matter. An analysis of within-group changes over trials also fails to clarify this issue, since only the nonvolunteer lost-choice group

showed a significant change, that is, a decrease in reading rate ($p < .03$). However, inspection of the data suggests that both effects may have taken place, possibly interacting with the characteristic of the subject population. In contrast to the average increases in reading rates among subjects in the free-choice groups, both volunteer and nonvolunteer subjects in the lost-choice groups showed an overall decrease in reading rate on the posttraining test. In the no-choice group, the rate of volunteers tended to increase and the rate of nonvolunteers tended to decrease after the training session. Variation among subjects and the size of the sample may have contributed to the failure to clarify this question in the present experiment.

The difference in change between volunteer and nonvolunteer subjects just missed significance at the traditional .05 level. However, the strong trend ($p = .06$) supports suggestions from earlier studies and extends the findings by Gordon (1976) that persons who seek out a particular change experience appear to benefit more from it than those who are assigned to it by others. Thus, the implications for clinical practice lie in the need for improvement of clinical techniques that would help a person become involved in a change program, even when initially referred by someone else.

The marginally significant difference between volunteers and nonvolunteers could be viewed as a reflection of the differences in experience with or enthusiasm about a reading skills program. The questionnaire data indicated that 31% of the nonvolunteer and 20% of the volunteers had previously experienced some speed-reading courses. Further, 67% of the subjects in each group indicated that they believed speed-reading courses can be effective. Thus, differential expectations of training effectiveness or past experience could not have contributed to the differences in reading rate changes that were obtained for the two populations.

An initial questionnaire assessed the subject's motivation to learn speed-reading techniques by asking how much time and money they would be willing to invest in a course. Volunteer and nonvolunteer subjects reported on the average that they would spend \$24 and \$29, respectively, and that they would

practice reading techniques 4.6 and 3.6 hours per week, respectively. Therefore, the two populations did not differ appreciably in their motivation to enhance their speed-reading skills.

In rating the experimenters' courtesy, competency, manners, and experimental conduct, all subjects tended to give favorable judgments. All group means were practically identical. On a 5-point scale (with 1 as the most favorable rating), the overall mean was 1.87. The present analogue to treatment is not complete. In clinical practice deprivation of treatment choice is rarely explicit. On the other hand, the analogue is more conservative, since agency-referred clients are often sent for treatment of a problem that they do not accept as requiring any personal change. In this study, both groups reported interest in working toward better reading skills. Thus the additional imposition of "the problem" in many clinical cases should yield stronger effects of the volunteer variable than was obtained here.

The overall findings of this experiment are consistent with the hypothesis that increased freedom of choice enhances performance in a change program. Within the limitations of the present study, this effect was more strongly demonstrated for the freedom to decide among training methods than for the difference in the source of referral to the experiment. Further tests of these hypotheses are needed to indicate whether generalization is warranted from the laboratory findings to long-term programs with clients who present a disturbing problem situation.

Reduction of Autonomic Arousal in Alcoholics: A Comparison of Relaxation and Meditation Techniques

Jerry C. Parker and Gary S. Gilbert

Veterans Administration Hospital, Columbia, Missouri and
University of Missouri—Columbia

Richard W. Thoreson

University of Missouri—Columbia

To investigate and compare the effects of progressive relaxation training and meditation training on autonomic arousal in alcoholics, 30 subjects were selected from a population of alcoholics in a Veterans Administration hospital substance-abuse program. The subjects were randomly assigned to one of the following three experimental conditions: (a) progressive relaxation training group, (b) meditation training group, or (c) quiet rest control group. All groups met for 3 weeks during which state anxiety, blood pressure, heart rate, and spontaneous galvanic skin responses were measured. The measures were designed to assess the treatment effects following the first training session and at the end of the total training period. The results indicate that both progressive relaxation training and meditation training are useful for reducing blood pressure in alcoholics. In addition, significant differences between the groups in the effectiveness of the relaxation procedures were found. Meditation training induced blood pressure decreases at an earlier point in the 3-week training period and affected decreases in systolic blood pressure that progressive relaxation training did not. These results support the idea of considerable specificity of response to relaxation techniques.

Recent authors (Benson, Beary, & Carol, 1974; Bernstein & Borkovec, 1973) have discussed the usefulness of progressive relaxation training and meditation training as treatments for stress-related disorders. In general, these authors have portrayed the techniques as potentially effective treatments for a number of problems including hypertension, insomnia, tension headaches, and generalized anxiety.

Alcoholism and other forms of substance abuse are also disorders for which relaxation techniques may have utility. Preliminary support for this possibility has been provided by studies assessing the effects of meditation on self-reports of substance usage (Benson, 1974;

Benson & Wallace, 1972; Shaffi, Lavelly, & Jaffe, 1974, 1975; Winquist, 1973). Although the mechanism by which relaxation techniques might affect drinking behavior is unknown, two possibilities appear tenable. First, relaxation techniques might serve as a direct substitute for the reduced arousal that follows alcohol consumption. If this were the case, such techniques might be useful for alcoholics as coping techniques in stressful situations. Second, relaxation techniques might lead to a generalized state of lowered arousal. Such a state of lowered arousal would, in turn, tend to deprive alcohol of its hypothesized tension-reducing capacity, since a relatively lowered state of arousal would already exist. As a consequence, less direct reinforcement of drinking behavior would theoretically occur as a result of the use of alcohol.

Further credence in the possible role of relaxation techniques in the treatment of al-

This article is based on a doctoral dissertation submitted by the first author to the Graduate School of the University of Missouri—Columbia.

cohol abuse is provided by studies investigating the relationship between anxiety, stress, and alcoholism. Steffen, Nathan, and Taylor (1974) found significant negative correlations between blood alcohol levels and electromyographic response in alcoholics, suggesting a tension-reducing effect of alcohol. Miller, Hersen, Eisler, and Hilsman (1974) compared alcoholics and social drinkers in a simulated interpersonal situation requiring assertive behavior. The alcoholics significantly increased their operant responses to obtain alcohol, but the social drinkers did not, suggesting that alcoholics may be more inclined to drink in response to social stress. Higgins and Marlatt (1975) studied the fear of interpersonal evaluation as a determinant of alcohol consumption in male social drinkers and found that subjects who expected to be evaluated in a second study drank significantly more alcohol than subjects who did not expect to be evaluated. The results of this study are suggestive of the possible role of stress, particularly when interpersonal in nature, in the development and maintenance of problematic drinking.

Although the tension-reduction hypothesis of alcoholism has not been firmly established (Cappell & Herman, 1972), the above studies are suggestive of possible dynamics involving anxiety, stress, and/or fear of interpersonal evaluation. Accordingly, relaxation techniques with reported success in reducing arousal (Benson et al., 1974; Bernstein & Borkovec, 1973) are worthy of consideration as a treatment strategy for alcoholics.

The purpose of the present study is to investigate the usefulness of relaxation techniques for reducing self-reported anxiety and autonomic arousal in alcoholics. Two divergent techniques, progressive relaxation training and meditation training, were included in the design for comparative purposes, since they may vary considerably in their effectiveness and in the dependent measures that they affect.

Method

Subjects

Subjects ($N = 30$) for this study were drawn from a population of male alcoholics on a substance abuse

unit of a Veterans Administration hospital. The mean age for the subjects was 45.1 years, and the mean educational level was 11.3 years. The subjects were generally of middle socioeconomic status, and the mean number of years of heavy drinking, as reported by the subjects, was 12.0. Subjects with evidence of psychosis, severe cerebral dysfunction, serious physical impairment, or illiteracy were omitted. In addition, subjects receiving psychotropic medications or having had previous relaxation or meditation training were not included. After the remaining patients were judged by the unit physician to be detoxified and after they had agreed to remain in the hospital for the duration of a 1-month treatment program, the State-Trait Anxiety Inventory (STAI), developed by Spielberger, Gorsuch, and Lushene (1970), was administered. Those patients with trait anxiety raw scores above 30 were selected for the study. The cutoff score was used because subjects with initially low anxiety would not permit an accurate assessment of the usefulness of the relaxation techniques. Two subjects were dropped on the basis of the cutoff score.

Groups

The selected patients were assigned by means of a table of random numbers to one of the following three treatment conditions:

1. Progressive relaxation training (PRT) group. The PRT treatment condition was operationalized by using the seven muscle group methodology of Bernstein and Borkovec (1973), which involves the systematic tensing and relaxing of various muscles. Subjects ($n = 10$) in this condition received 5 minutes of instruction in the rationale and exercises of PRT and then were exposed to 3 weeks of PRT practice, with the group meeting three times per week for $\frac{1}{2}$ hour each session. The first and last training sessions were individual sessions with the experimenter for the purpose of measurement. The middle sessions were conducted in a group setting with the 15-minute PRT instructions presented on a tape recorder and played in a quiet room with the lights turned low.

2. Meditation training (MT) group. The MT treatment condition was operationalized by using the methodology of Beary and Benson (1974). This methodology involves a comfortable position, a quiet environment, a passive attitude, and the silent repetition of the word *one* on every exhalation. Subjects ($n = 10$) in this condition received 5 minutes of instructions in the rationale and procedures of MT and then were exposed to 3 weeks of MT practice, with the group meeting three times per week for $\frac{1}{2}$ hour each session. The first and last training sessions were individual sessions with the experimenter for the purpose of measurement. The middle sessions were conducted in a group setting, with MT instructions presented on a tape recorder and played in a quiet room with the lights turned low. The first 2 minutes of the tape reviewed the MT tech-

nique and were followed by 13 minutes of silence, during which time the meditation was practiced.

3. Quiet rest control (QR) group. Subjects ($n = 10$) in this condition received 5 minutes of instruction in the desirability and benefits of relaxation, although no specific relaxation techniques were taught. Subjects were told simply to sit quietly with their eyes closed and to allow themselves to relax. They were then exposed to 3 weeks of QR sessions, with the group meeting three times per week for $\frac{1}{2}$ hour each session. The first and last QR sessions were individual sessions with the experimenter for the purpose of measurement. The middle sessions were conducted in a group setting, with the QR instructions presented on a tape recorder and played in a quiet room with the lights turned low. The first 2 minutes of the tape reviewed the QR instructions and were followed by 13 minutes of silence, during which time the quiet rest occurred.

Procedure

Subjects received a brief orientation interview by the experimenter, and permission for inclusion in a research study was obtained. The first session, an individual session with the experimenter, was conducted in a quiet room with the subject seated comfortably in a recliner facing away from the physiological recording equipment. The first part of the initial training session (5 minutes) was devoted to specific instruction in the particular treatment that the subject was to receive, and a 10-minute pretreatment measurement period immediately followed during which the physiological measures and the state anxiety data were collected. After this measurement period, the first 15-minute training tape was presented, and a 10-minute posttreatment measurement period followed in which the physiological measures and the state anxiety data were again collected. A brief period was provided after the second measurement period for questions from the subjects or further instructions, if needed.

The remaining training sessions, except for the final one, were conducted in a group setting over a 3-week treatment period. Each group meeting was $\frac{1}{2}$ hour in duration, with all groups meeting collectively for the first 15 minutes to control for motivational and expectancy variables. During this collective meeting, the rationale for relaxation therapy was briefly reviewed, and subjects were instructed to practice twice daily between group sessions.

The 15-minute tape-recorded training session followed, with each experimental group meeting separately in a quiet, dimly lighted room. The final training session, an individual session with the experimenter, again involved the collection of pretreatment and posttreatment measures.

Subjects who did not attend at least seven training sessions were dropped from the study. One subject from the QR group who had medical complications during his hospitalization was dropped for this reason. Another subject in the PRT group who dis-

charged himself from the hospital against medical advice was also dropped.

Measures

The following measures were designed to assess whether or not the treatments had immediate effects following the initial training session. To control for fluctuations due to the subjects' hospital activities, these measures were all collected in the mornings between the hours of 8:00 a.m. and 10:00 a.m.

1. The state anxiety portion of the STAI was administered during the pretreatment measurement period and the posttreatment measurement period of the initial training session.

2. Arterial blood pressure readings were taken on a standard medical manometer during the pretreatment measurement period and the posttreatment measurement period of the initial training session.

3. Heart rate measures were taken using the radial pulse method during the pretreatment measurement period and the posttreatment measurement period of the initial training session.

4. Skin conductance measures (spontaneous galvanic skin response; GSR) were recorded on a Lafayette Datagraph Model 76016 for a 2-minute interval during the pretreatment measurement period and the posttreatment measurement period of the initial training session. Spontaneous skin conductance fluctuations greater than .6 k Ω were scored by an independent observer unaware of the subjects' treatment condition. Beckman silver-silver chloride electrodes were attached to the first and third fingers of the left hand using Beckman electrode paste, and a 5-minute rest period was arranged during the pretreatment measurement period before the skin conductance measures were taken.

To assess the total training effects of the 3-week treatment program, STAI, blood pressure (BP), heart rate, and spontaneous GSR measures were also collected at the end of the final training session.

Results

The results of this study were analyzed in a two-way analysis of variance (Groups \times Trials) design with repeated measures on one factor. The pretreatment group means for state anxiety, BP, heart rate, and spontaneous GSR were not significantly different.

Session 1 Effects

State anxiety. The results from the 3×2 analysis of variance (ANOVA) on the STAI measures over Session 1 found the main effect for trials to be significant, $F(1, 27) = 43.49$, $p < .001$, indicating that the combined groups

Table 1
Mean State Anxiety Raw Scores Over the Initial Training Session and the 3-Week Training Period

Group	Measurement period		
	Session 1		Post final session
	Pre	Post	
Relaxation	45.5	35.2	28.8
Meditation	44.7	35.8	30.1
Control	46.5	41.6	36.6

reported less anxiety following Session 1, but no differences between the groups were found (see Table 1).

Blood pressure. The results from the 3×2 ANOVA on the systolic blood pressure measures over Session 1 found the interaction (Groups \times Trials) to be significant, $F(2, 27) = 4.68, p < .05$ (see Table 2).

For the systolic BP interaction, the group mean systolic BPs were significantly different from one another following their respective treatments, $F(2, 30) = 3.71, p < .05$. A Newman-Keuls probe found the MT group to be significantly lower than the PRT group ($r = 3, df = 30, p < .05$; see Winer, 1962, p. 80). The performance of the QR group, however, was not significantly different from that of

the PRT group or the MT group. The MT mean systolic BPs were significantly lower at the end of Session 1, $F(1, 27) = 11.52, p < .01$. The PRT and QR means were not significantly lower at the end of Session 1.

The results from the 3×2 ANOVA on the diastolic BP measures over Session 1 found the interaction (Groups \times Trials) to be significant, $F(2, 27) = 8.81, p < .01$ (see Table 2).

For the diastolic BP interaction, the MT diastolic BP mean was significantly lower at the end of Session 1, $F(1, 27) = 10.11, p < .01$. In contrast, the QR diastolic BP mean was significantly higher at the end of Session 1, $F(1, 27) = 6.77, p < .05$.

Heart rate. The results from the 3×2 ANOVA on the heart rate measures over Session 1 found the main effect for trials to be significant, $F(1, 27) = 26.70, p < .001$, indicating that the combined groups showed decreased heart rate following Session 1, but no differences between the groups were found (see Table 3).

GSR. The results from the 3×2 ANOVA on the spontaneous GSR measures over Session 1 found the main effect for trials to be significant, $F(1, 27) = 15.67, p < .001$, indicating that the combined groups showed decreased spontaneous GSRs following Session 1, but no differences between the groups were found (see Table 4).

Mean Blood Pressures Over the Initial Training Session and the 3-Week Training Period

Group	Measurement period		
	Session 1		Post final session
	Pre	Post	
	Systolic		
Relaxation	118.0	117.5	115.0
Meditation	109.5	104.5	102.5
Control	109.5	110.5	119.0
	Diastolic		
Relaxation	84.0	81.5	78.0
Meditation	77.0	71.5	69.5
Control	71.5	76.0	80.5

Total Training Effects

State anxiety. The results from the 3×2 ANOVA on the STAI measures collected at the beginning of the first session and the end

Table 3
Mean Heart Rates/Min Over the Initial Training Session and the 3-Week Training Period

Group	Measurement period		
	Session 1		Post final session
	Pre	Post	
Relaxation	88.6	76.1	80.4
Meditation	86.8	80.6	76.9
Control	88.4	83.9	87.0

of the final session found the main effect for trials to be significant, $F(1, 27) = 50.80$, $p < .001$, indicating that the combined groups reported less anxiety at the end of the final training session than at the beginning, but no differences between the groups were found (see Table 1).

Blood pressure. The results from the 3×2 ANOVA on the systolic BP measures collected at the beginning of the first session and the end of the final session found both the main effect for groups, $F(2, 27) = 3.74$, $p < .05$, and the interaction (Groups \times Trials), $F(2, 27) = 11.16$, $p < .001$, to be significant (see Table 2).

For the systolic BP analysis, the group systolic BP means were significantly different from one another at the end of the final training session, $F(2, 38) = 7.54$, $p < .01$. A Newman-Keuls probe found that the MT group was significantly lower than both the PRT group ($r = 2$, $df = 38$, $p < .01$) and the QR group ($r = 3$, $df = 38$, $p < .01$). The MT mean systolic BP was significantly lower at the end of the final training session, $F(1, 27) = 7.38$, $p < .05$. The QR mean systolic BP was significantly higher at the end of the final training session, $F(1, 27) = 13.59$, $p < .001$.

The results from the 3×2 ANOVA on the diastolic BP measures collected at the beginning of the first session and the end of the final session found the interaction (Groups \times Trials) to be significant, $F(2, 27) = 12.90$, $p < .001$.

For the diastolic BP interaction, the PRT and MT mean diastolic BPs were significantly

lower at the end of the final training session, $F(1, 27) = 5.58$, $p < .05$, and, $F(1, 27) = 8.72$, $p < .01$, respectively. The QR mean diastolic BP was significantly higher at the end of the final training session, $F(1, 27) = 12.55$, $p < .01$.

Heart rate. The results from the 3×2 ANOVA on the heart rate measures collected at the beginning of the first session and the end of the final session found the main effect for trials to be significant, $F(1, 27) = 11.31$, $p < .01$, indicating that the combined groups had lower heart rates at the end of the final training session, but no differences between the groups were found (see Table 3).

GSR. The results from the 3×2 ANOVA on the spontaneous GSRs collected at the beginning of the first session and the end of the final session found no significant effects (see Table 4).

Discussion

Conclusions from Session 1 Analyses

With regard to whether PRT and MT have effects over a single treatment session, the results indicate that on several dependent variables, they were not significantly superior to control procedures. Although PRT and MT led to reports of less anxiety, slower heart rates, and fewer spontaneous GSRs, control procedures appeared to produce similar changes. These findings suggest that simply instructing subjects to "rest quietly" on their own is as effective as PRT or MT for inducing decreased self-reported anxiety, lowered heart rates, and decreased spontaneous GSRs.

The control procedures and PRT, however, were not as effective when systolic BP and diastolic BP were the dependent variables. The study of systolic BP over Session 1 indicates that the performance of the MT group decreased significantly during the first session, whereas, that of the PRT and QR groups remained approximately the same. Moreover, the analysis of diastolic BP changes over Session 1 indicates that the MT group decreased significantly during the first session, whereas the PRT group remained approximately the same, and the QR group increased significantly. In summary, PRT and

Relaxation	5.8	1.2	2.5
Meditation	7.1	2.7	3.0
Control	3.3	1.8	4.8

Note. Measures are the number of fluctuations greater than .6 kΩ per 2 minutes.

MT are not more effective than control procedures when self-reported anxiety, heart rates, and spontaneous GSRs are measured. However, MT is significantly more effective than PRT and control procedures when systolic BP and diastolic BP are measured.

Conclusions from Total Training Period Analyses

With regard to whether PRT and MT have effects over a 3-week training period, the results are generally analogous to the Session 1 analyses. All three groups showed decreases in self-reported anxiety and heart rates, but statistically significant differences between the groups were not found. The data suggest that subjects who are told to rest quietly relax as well as PRT and MT subjects when state anxiety scores and heart rates are the dependent measures. No significant training effect was demonstrated for the spontaneous GSR measure, indicating that the Session 1 effects did not last over the entire training period.

Group differences were again found on the systolic BP and the diastolic BP measures. The systolic BP analysis showed that the MT group decreased significantly, the PRT group remained approximately the same, and the QR group *increased* significantly. The diastolic BP analysis showed that both the PRT and the MT groups decreased significantly while the QR group *increased* significantly. In summary, PRT and MT do not affect self-reported anxiety or heart rates over a 3-week training period, but they do affect systolic and diastolic BP in the direction of decreased arousal.

Implications

The results of this study suggest that persons have considerable "control" over the relaxation process, even when formal relaxation techniques are not being used. In terms of heart rates and spontaneous GSRs, the QR condition affected significant decreases on several measures. This finding is in contrast to the findings of several other studies (Beary & Benson, 1974; Wallace, 1970; Wallace & Benson, 1972) and may stem from the fact that expectancy, motivation, and attention ef-

fects were carefully controlled in the present research. Since the groups in this study met collectively when the rationale for relaxation was explained, the QR subjects had the same "expectancy" for benefits as did the experimental groups. Accordingly, the QR subjects were provided with a set that elicited a strong "desire" to relax.

A perusal of the typical research in the area of relaxation shows that such careful control of expectancy and attention is not usually the case. For example, in the typical ABA designs, trained meditators are instructed to "sit with eyes closed," then to "meditate," and then to "sit with eyes closed" again. The independent variable of meditation is manipulated in such designs, but expectancy is too. Subjects are quite probably given subtle cues indicating that they are supposed to "try" in the meditation condition, at least more so than when "sitting with eyes closed." In the Wallace and Benson (1972) research, the subjects were fully aware of the purpose of the study and had an investment in proving that meditation was effective. The present study suggests that expectancy and motivation are important variables that must be controlled in relaxation research, since subjects can affect considerable decreases in arousal on certain dependent variables with only positive expectancies and motivations operating.

A second implication of this study is that a single dependent variable is not likely to be sufficient for satisfactorily evaluating the effects of a relaxation procedure. Both systolic and diastolic BP differentiated between the groups in this study, but heart rates, spontaneous GSRs, and self-reports did not. Several studies in the literature of both relaxation training and meditation have used self-reports exclusively, and such reliance on a single dependent measure can sometimes be misleading. In the present study, systolic and diastolic BP measures were the most sensitive to differences between the groups.

A third implication is that PRT and MT differ substantially in their efficiency for inducing decreased autonomic arousal as measured by BP. In the systolic and diastolic BP analyses over Session 1, the MT group showed significant decreases, whereas, the PRT group

did not. In the systolic and diastolic BP analyses across the total training period, the MT group continued to show significant decreases, whereas the PRT group showed a significant decrease in diastolic BP only. On the basis of these findings, MT is a more efficient relaxation technique than is PRT when BP is a relevant variable.

A fourth, most intriguing, implication of this research is that efforts at relaxation can sometimes be stressful. In the analysis of diastolic BP over Session 1, the QR group showed a significant *increase* in arousal. Although heart rate, spontaneous GSR, and state anxiety scores decreased in association with the QR procedure, diastolic BP increased. This finding leads to the hypothesis that "cognitive activity" may increase in a stimulus-deprived situation as was found in the QR condition. Whereas the experimental groups had an activity to perform (either mental or physical exercises), the control group did not. All three groups appear to have received the benefits of a sedentary physical state, but only the experimental groups received the benefits associated with restricted attention. The restricted attention apparently reduced the likelihood of experimental subjects thinking about current problems and/or anxiety-arousing situations as seemed to occur with the QR control subjects. The experimental groups may have escaped such cognitive activity by the demands of the relaxation task. The findings of this study suggest that the MT procedure was the most effective experimental condition in a number of the analyses, and the concept of restricted attention may help explain these results.

Finally, with regard to the question of whether relaxation techniques are potentially useful in the treatment of alcoholism, the data are encouraging. The alcoholic subjects in this study clearly experienced decreases in autonomic arousal and self-reported anxiety, with MT tending to be the most efficient treatment condition. Using only a 5-minute instruction period, significant decreases in arousal were obtained during the first training session in both the PRT and MT groups. In general, these decreases were maintained over a 3-week training period with only group support. Such

benefits are at a small cost in terms of staff time, which makes the relaxation techniques practical for substance abuse programs. Also, the alcoholics in this study accepted the relaxation procedures with interest and cooperation. None of the subjects refused to participate or expressed dissatisfaction with the relaxation procedures.

As a cautionary note, demonstrating the efficiency of relaxation techniques for reducing autonomic arousal in alcoholics is not equivalent to demonstrating their usefulness as direct treatments for alcoholism. Long-term studies are required to assess whether alcoholics can be trained to use relaxation techniques on a regular basis over an extended period of time. Moreover, will such extended usage result in a generalized reduction in autonomic arousal and/or decreased rates of alcohol consumption?

Sex and Worker Acceptance of a Former Mental Patient

Amerigo Farina, Pauline J. Murray, and Thomas Groh
University of Connecticut

This is the fifth in a series of studies measuring the acceptance accorded to former mental patients. The procedure was to send a confederate in the guise of a job applicant to be evaluated by a worker already on the job. The workers were told either that the applicant was an ex-mental patient or that he was an ordinary applicant, and for each condition the confederate was calm for half of the subjects and nervous for the rest. The studies revealed that women are more accepting of former patients than men and that men are more accepting of female than male ex-patients. Nervous applicants were rejected by workers of both sexes.

Persons who experience difficulty in adjustment are viewed in a grossly unfavorable way by virtually all members of our society (Nunnally, 1961). Opinions are especially negative toward those who are hospitalized, apparently because hospitalization indicates very serious mental problems (Lawner, 1966). This leads to the gloomy conclusion that those who are least able to deal with thorny interpersonal situations and are hospitalized for this reason will find their problems magnified when they return to the community. Research into various facets of interpersonal interaction shows that this is precisely what happens (Farina, Gliha, Boudreau, Allen, & Sherman, 1971; Farina, Holland, & Ring, 1966; Farina, Thaw, Lovern, & Mangone, 1974).

A particularly important area for community adjustment is employment, since self-esteem and social status are closely tied to the job one has. Moreover, having enough money for even basic necessities such as food will typically entail working, and if an ex-patient cannot find a job, the patient may be forced to return to the hospital. The research that has been done on job finding has been

limited to male subjects. However, that research makes it amply clear that males are denied jobs if they have been in a mental hospital. Employers will openly *say* that they do not like hiring ex-mental patients (Olshansky, Grob, & Malamud, 1958). With actual behaviors, it was found that employment interviewers estimated a male applicant's probability of getting a job as significantly lower, and they were reliably less friendly toward him when he revealed a history of mental illness in comparison to when he did not (Farina & Felner, 1973).

In view of these data, some wholly unexpected findings were obtained in a series of four studies, all using the same procedure (Farina, Felner, & Boudreau, 1973; Farina & Hagelauer, 1975). Female department store clerks met a female confederate in the guise of a job applicant and were asked to evaluate her as a potential co-worker. Half were told that the applicant was an ex-mental patient, and the rest were told that she was an ordinary job seeker. Unlike all prior studies of males, the women were no less accepting of the ex-mental patient than of the normal applicant. The study was replicated with female workers in a hospital, using a different female confederate, and the identical results were obtained. There followed another replication at the same hospital, but this time the subjects were male workers who met a male confederate. It was then found that males

The present study was, in part, financed by Research Grant GS-31030X from the National Science Foundation.

strongly rejected the applicant with a history of mental illness. To determine if it was sex of the subject or sex of the mental patient that accounted for the differences, a fourth replication was carried out. A new group of female department store clerks met a different male confederate, and no difference was found in degree of acceptance accorded to the applicant whether he was perceived as an ex-patient or as normal.

Attitude studies hardly explain these clear sex differences in acceptance of former mental patients. Nunnally (1961) found no sex differences in attitudes in any of the numerous studies that he has done. In a later attitude study (Farina et al., 1973), it was found that males in comparison to females expressed a greater liking for and a greater willingness to work with ex-mental patients. This kind of incongruity between attitudes and behaviors is not peculiar to the topic of mental illness. It has been found in a number of areas (e.g., Farina & Holzberg, 1967; Kutner, Wilkins, & Yarrow, 1952).

Thus, prior behavioral studies have shown that females are perfectly willing to accept either a male or a female as a co-worker even if the applicant has been mentally ill. Male workers, however, strongly reject a male applicant if he has a history of mental illness. How males would act toward a female applicant who has been in a mental hospital has not been determined, and this is one purpose of the present study. In the prior studies an additional variable, being tense and nervous or being calm, was also investigated. With half of the subjects in the mentally ill condition and half in the control condition, the "applicant" acted visibly tense and nervous. Calm and relaxed behavior was displayed with the remaining subjects. In all four studies the nervous applicant was unambiguously rejected. This manipulation is also carried out in this investigation to determine if tense people are disliked generally or whether this effect, too, is sex related.

Method

The subjects of the study were 48 males employed in the physical plant division of a state university. The nature of the work they did was quite variable, ranging from supervision of heating plant operations

to janitorial work. They were contacted by a supervisor and were informed that the possibility of using workers to evaluate job applicants was being investigated. Therefore, they were told that workers were needed to interview and give their opinion of a potential co-worker, and they were asked to volunteer their help during regular working hours. Those who volunteered were contacted, and a time was set for the interview to take place. All but 1 man who volunteered actually became subjects of the study, and 12 were randomly assigned to each of the four cells. The single exception was a man who expressed the conviction that we were trying to fire people like him, and he was excused from the study.

The workers were seen in offices belonging to the physical plant division. It was explained to them that workers already on the job knew that job best and, therefore, they would meet a job applicant and evaluate how well the new person would do if placed in the same department in which they worked. They were further told that the university wanted to see how disadvantaged people (former mental patients) would do on certain jobs. To find out, they were told that some workers would meet former mental patients who were interested in working for the university and that other workers would meet ordinary applicants to provide comparison data by means of which the suitability of ex-patients could be judged. To avert suspicion in the event that the employees compared notes, they were told that one applicant might be seen by several workers.

Each subject was asked to talk to the applicant and to form a basic impression about her. This was stressed as most important, since later, in private, he was to indicate how he judged the applicant would do if hired. He was also asked to describe the essentials of his work to help her decide about accepting the job, if it were offered. As part of a brief background statement about the applicant, half of the workers were then told that the person they were about to meet was a former mental patient, whereas the rest were informed that she was an ordinary job applicant. Actually, everybody met the same confederate,¹ a female undergraduate student in her early 20s. She was introduced with different names, and she changed clothing several times in a given day to avert suspicion. The workers generally seemed pleased to participate in the project and appeared to believe the experimenter.

The confederate related the same personal history in all conditions. She reported having graduated from high school and working as a clerk in a hardware store. She also said that she had worked in a grocery store and had been employed as a secretary. However, with half of the workers in the mental patient condition and half in the control condition, she behaved in a calm, relaxed manner, whereas with the rest she was tense and anxious. The be-

¹ We would like to thank Maureen Kohler for doing this work.

havior selected to indicate anxiety was the same as was used in the prior four studies. In the anxious condition the confederate seldom looked the employee in the eye, only occasionally stealing a glance. She kept her head down while frequently wringing her hands, and periodically she swallowed as if her throat were dry. To avoid possible changes in behavior as a function of believing the worker considered her normal or blemished by a history of mental illness, she was kept ignorant of what the subjects had been told.

After the confederate had described her work experience, the employee was instructed to describe his job. The applicant was then thanked and dismissed, and a postexperimental questionnaire was read to the worker, who responded to the items verbally. None of the workers seemed suspicious about any aspect of the study. We believe that participation in the study during regular working hours and at the request of the supervisor helped to avert skepticism. We further believe that the effort being made by the university during that period to hire from populations underrepresented by the employees also helped. The true nature of the study was never revealed both to insure subject naiveté and because disclosure seemed more harmful than nondisclosure.

Results and Discussion

A central purpose of the present study was to determine the reception that would be given to a female former mental patient by male workers. To do this, the 15 items in the postexperimental questionnaire were analyzed using two-factor analyses of variance, with one factor being history of the applicant (mental illness—no mental illness) and the other component being the confederate behavior (tense—calm). For one of these items, a significant main effect ($p < .05$) for mental illness was found. When asked to describe the applicant's assets, the workers perceived her as having fewer assets if she had been in a mental hospital than if she had not. Although this finding was close to chance level (1 significant item in 15), it was anticipated that not all items would be equally revealing about unfavorable dispositions toward ex-patients. In our society people are expected to be helpful toward unfortunate others, like mental patients, rather than doing them harm. Consequently, as in the prior studies, the workers were not expected to express disfavor openly, such as by saying they would not get along with the applicant in the mental patient condition. However, the expression

of negative feelings was expected on items on which it was not obvious that the respondent was registering personal disfavor. One item viewed as especially subtle was the one inquiring about the assets possessed by the applicant. This reasoning is described in detail, and empirical support for it is presented in another publication (Farina, Chapnick, Chapnick, & Misiti, 1972). Therefore, even though only one item differed between conditions, the fact that it was a subtle item suggests that the history of hospitalization did lead the workers to reject the female applicant. However, this rejection is much milder than that shown toward a male applicant in a previous study (Farina et al., 1973).

There are also some significant interactions which indicate that these subjects have an unfavorable view of a female former patient. In the calm condition the confederate was described as significantly more tense when she was presented as a patient than when she was described as an ordinary job applicant. On the other hand, when nervous and tense, it was the normal applicant who was rated as more tense ($p < .05$). It seems that the normal applicant is expected to be calm, and when she is tense her nervousness is very salient. In contrast, the ex-mental patient is expected to be nervous, and she is seen as tense even when objectively the tension is not there. A similar pattern was found for the item asking how well the applicant would do the job if hired. A reliable interaction ($p < .05$) indicates that the normal person is expected to do better when calm, whereas a former patient is expected to do better when nervous. Possibly, better performance is anticipated and people are liked more when they behave in accordance with stereotypic beliefs. One of the studies reported by Farina et al. (1973, p. 366) strengthens this possibility, since the same results were found.

The findings concerning the calm—tense variable were consistent and quite clear. When tense, the confederate is expected to get along less well with other workers ($p < .05$), she is perceived as having fewer assets ($p < .001$) and more liabilities ($p < .001$), she is judged to be less reliable ($p < .05$), and she is thought to be less well adjusted

($p < .001$) and valuable ($p < .05$) than when she is calm.

Before considering the meaning of these results, we need to take note of the methodology used in this and the similar prior studies, since this bears on the conclusion we can draw. In each study, the subjects were a reasonably random sample of workers in that setting, and so we believe that other workers drawn from comparable populations would behave like our subjects if they were to face the same conditions. However, only one confederate was used in each study. The major problem with such a procedure was clearly recognized by Brunswik (1947) and forcefully described by Hammond (1948). In brief, if we want to determine how workers respond to an ex-mental patient, we need both a representative sample of workers and a representative sample of ex-mental patients. Of course, we can conclude that workers react unfavorably to at least one person—the confederate we used. But another individual, whose physique and personality are different, might not elicit the same reaction. Data pertinent to this issue were reported by Farina, Thaw, Felner, and Hust (1976). Those researchers examined how the social impact of stigmatizing conditions (including mental illness) was influenced by individual differences among people. Four confederates played the role of a normal or stigmatized person with subjects drawn from the same population. A given subject saw only one confederate in only one of the three roles. It was found that the effect of the stigmatizing conditions was reliably influenced by the individual characteristics of each confederate.

On the other hand, Farina et al. (1976) also found response patterns that were the same for all confederates; for example, when perceived as mentally retarded, each confederate was given reliably less painful shocks than when perceived as normal. Thus, individual differences among people do not necessarily invalidate all findings obtained with just one person. More important, the present study is the fifth in a series, all using identical procedures. The five experiments contained five different confederates, two males and three females, and were done in three different places of employment. Yet, the findings

are extremely consistent. For the calm-tense variable, we find that the confederate, when nervous, is always evaluated much less favorably. The mentally ill-normal results are also consistent, with males evaluating the confederate in the ex-mental patient condition less favorably than in the control condition and women responding the same in the two conditions.

What conclusions can we reasonably draw from this and the earlier studies? There appear to be two rather clear sex differences in the way that mental patients are treated. First, men appear to be unfavorably disposed toward members of either sex if they have been mentally ill, whereas women fully accept such a person. And second, focusing on the victim of the mental illness, a male is treated more poorly than a female even when they have identical psychiatric histories. The results from this series of five studies are surprising in view of the past studies that uniformly report that there are no sex differences of the sort that we have found. Leaving inconsistencies between the present and past studies aside for the moment, how are we to understand our findings? There are reports in the literature that suggest explanations.

Parsons and Bales (1955) have asserted that women are more concerned with ongoing interpersonal relationships than are men, whereas men focus more on goals in the future. The confederate acted in the same way both as a normal and as an ex-mental patient; women, perhaps, respond similarly in the two conditions because they are more influenced by the immediate behavior than by the cues about future threats from the former patient. On the other hand, men are more concerned about the future and may have rejected the applicant with the psychiatric history because of fears such as of a disruption in their work careers. As for the preference men show for female in comparison to male ex-mental patients, a possible explanation is that males are thought more likely to be aggressive and disruptive once hired. It has been reported that males are viewed as more disposed than females to react to stress with aggressive behavior

(Coie, Pennington, & Buckley, 1974). However, the evidence in support of these explanations is of uncertain value, since it is based on surveys of opinions. It appears likely that it is because attitudinal measures were used in the prior studies of social reactions to mental patients that the sex differences we found were so unexpected. By now it should be very clear that the attitudes that people express and what they actually do are not necessarily consistent. Hence, if we are interested in behavior, we should measure behavior as directly as possible.

The finding that nervous people are so unequivocally and strongly rejected has both theoretical and practical implications. On the theoretical level, it seems important to know why tense people are responded to so unfavorably. Perhaps such a response is limited to circumstances in which someone is to be judged as a worker and means only that anxious people are expected to do a poor job. But it seems likely that this reaction is much more general, and it may mean that nervous people evoke memories of negative events or promise to bring trouble in the future. Whatever is responsible, we can expect that tense people will be less readily accepted than calm individuals, and we can improve their social relationships if we can reduce the visibility of their tension. If mental patients are especially tense, as is widely believed, it might be particularly important to their readjustment at home if they can be helped to look more calm. Conceivably, the nervousness displayed by ex-patients is in part responsible for the difficulties that they encounter in finding a job.

Prospects for Faking Believable Deficits on Neuropsychological Testing

Robert K. Heaton, Harold H. Smith, Jr., Ralph A. W. Lehman,
and Arthur T. Vogt
University of Colorado School of Medicine

This study compared the results of 16 volunteer malingers with those of 16 cooperative, nonlitigating head-trauma patients on the Wechsler Adult Intelligence Scale, the Halstead-Reitan battery, and the Minnesota Multiphasic Personality Inventory (MMPI). The overall level of ability impairment shown by the malingers equaled that of the head-injury group, but different patterns of strengths and deficits were produced by the two groups on testing. The malingers also showed more severe personality disturbance on the MMPI. The test protocols were sent to 10 neuropsychologists, who made "blind" judgments as to whether each was probably produced by a malingerer or by a real head-injury patient. Neuropsychologists' diagnostic accuracies ranged from chance-level prediction to about 20% better than chance. Discriminant functions based on the neuropsychological test results and the MMPI, respectively, correctly classified 100% and 94% of subjects in both groups. In another large sample of head-injury patients, those who were involved in court actions and/or gave clinical evidence of faking were more likely to be classified as malingers by the discriminant functions.

Neuropsychological tests are widely used in clinical settings to help diagnose brain lesions. Their role in this context is usually ancillary. That is, they help predict the presence and nature of neurologic conditions, which must then be confirmed by procedures involving more cost, risk, and/or discomfort. On the other hand, because they directly measure abilities affected by brain damage, neuropsychological tests have a more definitive role when the questions being asked deal specifically with the behavioral consequences of neurologic conditions. Such consequences can be important in themselves, not merely as symptoms contributing to a medical diagnosis. For

the many brain-damaged patients whose conditions are neither grossly incapacitating nor immediately life threatening, it is important to know which abilities have been affected, the severity of the various deficits, and their probable impacts on the patients' everyday functioning (e.g., on social relationships and potential for working and living independently). In some civil and criminal court proceedings, there is also a need to define as precisely as possible the effects of brain lesions on adaptive abilities. In such cases a dollar value is to be placed on the disability resulting from a head injury, or legal competency is to be decided.

This project was supported in part by Biomedical Research Support Grant RR-05357 awarded by the Biomedical Research Support Grant Program, Division of Research Resources, National Institutes of Health.

To be valid for any of the purposes mentioned above, neuropsychological testing requires adequate effort on the part of the patient. Most people are inclined to do their best on tests, and most patients have more to gain by appearing capable than by emphasizing deficits. This is not always true, however, particularly when the test results are to be used to justify compensation or other claims. Thus, in testifying before the courts as an expert witness, the clinical neuropsychologist

chologist is frequently asked a difficult question: "Is it possible to exaggerate deficits on these tests or even to fake deficits that do not exist?" In some cases one can argue convincingly that the particular pattern of test results makes good sense neurologically, and that it is therefore unlikely that the patient was malingering. However, few (if any) clinicians have had experience with known malingerers, and no research has shown whether malingerers' neuropsychological test scores can be distinguished from those of nonmalingerers' brain-damaged patients.

The Minnesota Multiphasic Personality Inventory (MMPI) is often used in conjunction with neuropsychological tests to help determine the types and degrees of emotional disturbances that may be associated with neurologic impairment (Boll, Heaton, & Reitan, 1974; Dikmen & Reitan, 1977). MMPI scales and formulas have been developed for detecting conscious malingering and other test-taking attitudes that may affect MMPI profile validity or serve as moderator variables in profile interpretation (Anthony, 1971; Cofer, Chance, & Judson, 1949; Gough, 1947, 1950, 1954; Osborne, 1970). It is not known whether patients tend to display the same test-taking attitudes on the MMPI and on neuropsychological tests; if they do, MMPI signs of malingering might alert clinicians to the possible invalidity of neuropsychological protocols produced by the same patients. Also, there is some evidence that the MMPI may be helpful in identifying patients with functionally based neurological complaints (Shaw & Matthews, 1965).

The present study compares the results of some volunteer malingerers with those of nonlitigating head-injured patients on the MMPI and a detailed battery of neuropsychological tests. In addition, these test results were sent to 10 neuropsychologists to determine whether they could judge which protocols were produced by malingerers and which were produced by the patients with real head injuries.

Method

Subjects

The head-injury group was composed of 13 males and 3 females, with a mean age of 26.7 ($SD = 6.5$)

years and a mean of 11.9 ($SD = 1.6$) years of education. All of these patients had been referred for clinical neuropsychological evaluations, and all were considered to have put forth adequate effort on the testing. All had documented histories of traumatic head injuries, followed by at least 12 hours of unconsciousness, and had no history of any other neurological illness. At the times of testing, all of the patients had residual neurological deficits, but none had peripheral injuries to their upper extremities that would interfere with test performance. Also, none of these individuals were involved in civil or criminal court actions, and none were applying for disability income support.

The malingering subjects were recruited by the second author from his neighborhood, college classes, and church. These subjects were told that they would be given \$25 for taking the neuropsychological test battery and a \$5 bonus if they were successful fakers. Actually, all subjects were paid the \$30 regardless of how much they faked. Twenty subjects agreed to participate in the study as malingerers, but only 16 gave any evidence of actually malingering on the tests. The other 4 individuals earned normal scores on the entire neuropsychological test battery and were eliminated from the study.¹ There are two reasons for omitting them. First, the normal test scores would not have justified compensation in a real court case. Second, the purpose of this study was to learn whether patterns of neuropsychological deficits due to head injury can be distinguished from those faked by malingerers. The distinction between real deficits and no deficits is of little interest in this context.

The malingerers who were retained in the study included 11 males and 5 females. Their mean age of 24.4 years ($SD = 7.5$) was not significantly different from that of the real head-injury group, $t(30) = .94$, $p > .05$. Also, their mean of 12.9 years ($SD = 2.4$) of education was comparable to that of the head-injury group, $t(30) = 1.39$, $p > .05$. To provide an estimate of their actual intelligence, prior to their testing as malingerers, these subjects were administered the Shipley-Hartford Intelligence Scale (Shipley, 1940) under standard conditions; that is, they were asked to do their best. Using the system proposed by Paulson and Lin (1970) for predicting Wechsler Adult Intelligence Scale (WAIS) Full Scale IQ values from Shipley scores, we obtained a group mean of 113.2 ($SD = 7.5$).

Tests

Neuropsychological evaluations were administered by experienced technicians who were trained and

¹ One of these four individuals had started to fake, but he was so obvious about it that the technician severely reprimanded him and threatened to call the attorney who had supposedly referred him for testing. From that point on, the subject earned above average scores on all tests given.

supervised by the first author. The evaluations consisted of all 11 subtests of the WAIS (Wechsler, 1955) and all of the tests normally included in the Halstead-Reitan Neuropsychological Test Battery for adults. These latter tests, which are described in detail in Reitan and Davison (1974), include the Category Test; the Tactual Performance Test; the Speech-Sounds Perception Test; the Seashore Rhythm Test; the Finger Oscillation Test; Parts A and B of the Trial Making Test; the Reitan-Kl ve Sensory-Perceptual Examination, with the Tactile Form Recognition Test replacing Tactile Coin Recognition as the measure of dysstereognosis; the Aphasia Screening Test, including the testing of visuconstructive abilities; measures of grip strength, obtained with a hand dynamometer; the Grooved Pegboard and Static Steadiness Tests from the Kl ve-Matthews Motor Steadiness Battery; and the Reitan-Kl ve Lateral Dominance Examination. The MMPI was also administered to provide objective personality measures that might be differentially associated with real brain damage versus deliberate attempts to exaggerate pathology.

Numerous published studies have shown that the neuropsychological test battery used in this study is sensitive to focal and diffuse cerebral lesions caused by diverse neurologic conditions. (See reviews of this literature in Kl ve, 1974, and Russell, Neuringer, & Goldstein, 1970.) In addition, this battery is well suited to the task of cataloging residual strengths and deficits after a traumatic head injury, because it samples broadly the adaptive abilities that can be affected by cerebral lesions, such as, sensory, motor, cognitive, language, visuospatial, as well as other mental abilities. An additional advantage of the test battery approach is that it permits analysis of both the level and the pattern of test performance in making diagnostic inferences (Reitan, 1966). Given the test scores from the Halstead-Reitan battery, experienced clinicians have been able to use these complementary diagnostic methods to infer not only the presence and location of cerebral lesions but also their etiologies (Filskov & Goldstein, 1974; Reitan, 1964). Even though it may be very difficult for a clinician to discern whether one or a few poor test scores have been faked, a consideration of the pattern of strengths and deficits shown on more comprehensive testing may make such discrimination possible; that is, to fool the clinician on the test battery, the malingerer must show a pattern of results that is similar to patterns of scores earned by head-injury patients with real deficits.

Judges

Ten neuropsychologists provided independent "blind" ratings as to whether they thought each test protocol was produced by a malingerer or by a nonmalingerer head-injury patient.² The second and fourth authors participated as judges. However, at that time they had no knowledge of the numbers of subjects in each group and no previous

exposure to the test results of any of the subjects. The 10 judges differed greatly with respect to previous experience in interpreting the Halstead-Reitan battery: The range was 8 weeks to 18 years full-time equivalent, with 5 of the judges having 4 or more years of experience. Judges with varying experience were sought in order to assess the possible role of experience in increasing diagnostic accuracy.

Procedure

The technicians who tested the malingering subjects were not told about this study until after the data collection phase was completed. To replicate the usual testing situation as closely as possible, it was considered necessary for the technicians to test these subjects as real clinical patients. Therefore, these subjects were scheduled as litigating patients, referred by one of two Denver attorneys who had previously sent real patients for testing.³

In preparation for their neuropsychological evaluations, the volunteer malingerers were asked to pretend that they had suffered head injuries in accidents caused by other persons. Subjects were to consider themselves involved in litigation to determine how much financial compensation they would obtain from the persons responsible for the accidents or from the insurance companies involved. They were told to imagine that their everyday functioning (e.g., in school and vocational activities) had been much worse since their accidents, that their potential earning powers had been substantially reduced, and that they deserved all the money that the courts would allow them. It was explained that their psychological test results would help determine how large their settlements would be. They were encouraged to fake the most severe disabilities that they could, without making it obvious to the examiner that they were faking. They knew that it was necessary for the technicians to think that they were real clinical patients. The subjects were told nothing about the test battery beyond what is usually told to real patients—that they would be tested for a full working day; that the tests cover a variety of sensory, motor, and cognitive functions; and that the tests measure disabilities that result from brain injuries. They were also given some of the other background information that real trauma patients have: (a) a story about the accident, duration of coma and hospitalization, whether there was a skull fracture, whether seizures developed and, if so, what the seizures were like and how they were being treated (this infor-

² We are grateful for the assistance of Elgan Baker, Gordon Chelune, Charles Clelland, Igor Grant, Robert Ivnik, Charles Matthews, Homer Reed, and James Reed, who served as clinical judges.

³ We appreciate the permission granted by Neil Hillyard and Gerald McDermott to have malingering subjects scheduled for testing under their names.

mation was taken from the files of real head-trauma patients) and (b) a very general description of the neurological lab tests and clinical exams that they would have received if they had been real trauma patients.

The examiner technicians questioned whether 7 of the 16 malingerers had put forth optimal effort on one or more tests. The other 9 malingerers were successful in convincing the examiners that they had given their best performances during all of the testing.

Each test protocol sent to the neuropsychologist judges contained the following: (a) the subject's age, sex, years of education, present/most recent occupation, and time elapsed since the subject's real or pretended head injury; (b) the 3 IQ values and 11 subtest scaled scores on the WAIS; (c) the Halstead Impairment Index and scores on the Category Test (total error score, plus scores on the seven individual groups), Trail Making Test (time and error scores), Tactual Performance Test (times and numbers of blocks placed during all three trials plus Memory and Location scores), Speech-Sounds Perception and Seashore Rhythm Tests, Lateral Dominance Examination, and for each hand on the Finger Oscillation, hand dynamometer, Grooved Pegboard, and Static Steadiness tests; (d) xeroxed data sheets with individual responses recorded on the Aphasia Screening Test and Sensory-Perceptual Examination; and (e) *T* scores for the 3 validity scales and 10 standard clinical scales of the MMPI.

Judges were told of the general design of the study and were provided details of the subject selection procedures and instructions given to the paid malingerers. They knew that some of the subjects were malingerers and that some were non-malingering head-injury patients, but they were not told how many of each were in the total group. Judges were asked to consider each protocol, one at a time, and to make their judgments about the protocol without reference to the others. Furthermore, each judge was asked to consider the 32 protocols in a different random order. After reviewing each protocol, two decisions were required. The first was whether the protocol was probably produced by a malingerer or by a genuine head-injured patient. Second, the degree of confidence with which this first judgment was made was to be rated according to a 4-point scale: very sure, sure, fairly sure, unsure.

Results⁴

Table 1 presents the means, standard deviations, and *t*-test results for the malingering versus head-injury group comparisons on all test measures. The malingerers did as badly as the real head-injury patients in overall level of ability test performance; that is, there were no significant differences between the groups on the three WAIS IQ

values or on the two neuropsychological summary measures (Average Impairment Rating and Halstead Impairment Index). Also, the mean Full Scale IQ obtained by the malingerers when asked to fake was 17 points lower than their actual mean IQ as estimated with the Shipley-Hartford scale, $t(30) = 6.39$, $p < .001$. These results suggest that the malingering group did in fact fake deficits during neuropsychological testing.

Although there were minimal group differences in overall level of performance, the malingerers did differ from the real head-injury group in the pattern of strengths and deficits shown on testing. The real head-injury group did significantly worse than the malingerers on the Category Test; Part B of the Trail Making Test (error component); and on the Total Time, Memory, and Location components of the Tactual Performance Test. The malingerers did worse on the Speech-Sounds Perception Test, the Finger Oscillation Test, finger agnosia, sensory suppressions, hand dynamometer, and WAIS Digit Span. In addition, the malingerers showed (faked) more emotional disturbance on the *F* scale and on six clinical scales of the MMPI.

The neuropsychologist judges correctly classified from 50.0% to 68.8% of the subjects in this study. Sensitivity, or true positive rate for real head injuries, ranged from 43.8% to 81.3%. Specificity, or true negative rate for malingerers, ranged from 25.0% to 81.3%. Three somewhat different measures of diagnostic accuracy are more directly relevant to the clinical situation: the probability that the subject has a real head injury if the judge says he/she does; the probability that the subject is faking if the judge says he/she is; and the judge's overall efficiency, or total correct classification rate for the combined population of head-injury patients and malingerers. These three measures vary not only with the sensitivity and specificity of the judge but also with the prevalence of malingerers in the population being studied. In this study the prevalence rate of malingering was set arbitrarily at 50%, but in general

clinical or litigating populations the prevalence may be much different. Table 2 presents the ranges of these three diagnostic accuracy figures estimated for our 10 judges at three prevalence rates of malingering: 30%, 50%, and 70%. The computations involved are described in Galen and Gambino (1975). In general, the success of the judges

ranged from chance-level prediction to prediction rates about 20% better than chance. For most of the judges, sensitivity exceeded specificity; these judges would do best under the lowest malingering prevalence conditions. Conversely, in this study two judges correctly classified more malingers than head-injury patients, and they would do better

Table 2

Ranges of Diagnostic Accuracies Expected From 10 Neuropsychologists Adjusted for Prevalence of Malingering at Three Levels

Rate	<i>P</i> (I/+)	<i>P</i> (M/-)	Efficiency	Efficiency change from <i>P</i> (M) = .30
<i>P</i> (M) = .30				
Judges' range	.70-.85	.30-.50	.55-.70	—
Chance	.70	.30	.50	—
<i>P</i> (M) = .50				
Judges' range	.50-.70	.50-.69	.50-.69	-.10 to +.08
Chance	.50	.50	.50	.00
<i>P</i> (M) = .70				
Judges' range	.27-.50	.62-.85	.40-.70	-.20 to +.15
Chance	.30	.70	.50	.00

Note. *P*(M) = prevalence of malingers in the population being studied; *P*(I/+) = probability that the patient has a real head injury, if the judge says he/she does; *P*(M/-) = probability that the patient is faking if the judge says he/she is; efficiency = overall proportion of correct classifications to be expected from the judge, given a specified *P*(M).

whenever the prevalence of malingering is higher. The far-right column of Table 2 shows how changing prevalence rates can affect judges' overall efficiencies.

The relationship between the judges' total correct classification rates in this study and their amounts of previous experience in neuropsychology was not statistically significant, $r(8) = .27$. The median percentage of agreement for all possible pairs of judges was only 56 (range = 31%–75%). The relationship between confidence ratings (unsure to very sure) and prediction accuracy was computed for each judge using a point-biserial correlation; that is, confidence ratings for correct versus incorrect judgments were compared. These correlations ranged from $-.13$ to $.46$ ($df = 30$). There was a nonsignificant tendency for more experienced judges to more accurately assess their likelihood of being correct in their subject classifications; a product-moment correlation of $.24$ ($df = 8$) was obtained between judges' years of experience in neuropsychology and their point-biserial correlations for confidence ratings versus classification accuracy. The order in which cases were reviewed did not affect the probability of the cases being correctly identified by the judges, $r(30) = -.20$. Also, there was a nonsignificant correlation between subjects' severity of "impairment" on the neuropsychological test battery (Average Impairment Rating) and subjects' likelihood of being correctly identified by the judges, $r(30) = .17$.

Because the head-injury and malingering subjects did show different patterns of performance on testing, it seemed possible that these differences might permit classification of subjects with a greater degree of accuracy than that achieved by the judges. Two stepwise discriminant function analyses (Nie, Hull, Jenkins, Steinbrenner, & Bent, 1975) were performed, one using the neuropsychological variables and the other using the MMPI variables listed in Table 1. The optimal neuropsychological discriminant function cutoff correctly classified all subjects in both groups. The optimal MMPI function cutoff missed only one subject in each group.⁵

It was not possible to recruit more malingerers for direct cross-validation of the

discriminant functions. However, a number of head-injury patients not included in the function development had received clinical evaluations in our neuropsychology laboratory, and their results were available for indirect cross-validation of the functions. Of these patients, 12 had complete neuropsychological data only, 14 had complete MMPI results only, and 62 had both types of data complete. Forty-one of these 88 patients were known to be involved in civil or criminal court actions at the times of testing, and 5 litigators and 1 nonlitigator were considered by the examiners to have been obviously faking on the tests. Thus, 42 of the head-injury patients had reason to exaggerate pathology and/or gave strong clinical evidence of doing so. Another 42 were known not to be involved in court cases and were rated by the examiners as having put forth adequate effort on testing. Excluded from consideration were 2 patients for whom it was uncertain whether they were litigating and 2 who had had cerebrovascular accidents in addition to head injuries.

The malingering discriminant function formulas were applied to the remaining 84 patients. Of the 42 patients who were involved in court cases or who had given strong clinical evidence of exaggerating deficits, 27 (64.3%) were classified as being malingerers by one or both formulas. Of the 42 who had no obvious evidence of or reason to exaggerate pathology, only 11 (26.2%) were classified as malingerers by one or both formulas. The resulting chi-square of 12.95 ($df = 1$, $p < .001$) indicates that obvious fakers and patients involved in civil or criminal court proceedings were significantly more likely to be called malingerers by the formulas.

Discussion

It is difficult to guess what proportion of clinical patients exaggerate deficits on neuropsychological testing. However, the question of exaggeration probably should be considered more often than it is, particularly when there are obvious reasons for the patient not

⁵ Due to the length of these discriminant function formulas, they are not given here. They can be obtained from the first author.

to do his or her best. It is likely that the prevalence of malingering is especially high among patients involved in compensation litigation or competency disputes in criminal trials. This group comprises half of all head-injury referrals to our laboratory. In addition, there are probably other social and personality factors that cause some patients to fake or exaggerate disability. For example, for some individuals the expectation of special care or attention in the family, greater concern from the treating physician, or release from performance expectations might serve as strong inducement for emphasizing real or imagined deficits.

The overall correct classification rates obtained by the neuropsychologist judges in this study are rather modest, but it is unlikely that any of them have had previous experience with known malingerers. It would seem that the judges' prior experience was only indirectly relevant to the questions asked in this study, and this may explain the low correlations between amount of experience and accuracy of judgments. Furthermore, judges were deprived of such potentially useful information as details of the patients' injuries, findings of neurological clinical and laboratory tests, how the recovery periods had gone, how well the patients had done in life prior to their injuries, behavioral observations made by the neuropsychological technicians, and even some test data (verbatim responses on the WAIS). All of this information is usually available in the clinical situation and might contribute to the diagnostic accuracy of the clinician. However, the primary concern of the present study was the value of the test scores in making clinical judgments, and our judges were provided with the same information used in previous studies of clinical interpretation with the Halstead-Reitan battery (Filskov & Goldstein, 1974; Reitan, 1964).

Our group comparisons on the neuropsychological test battery reveal that malingerers can show significant abnormalities on testing, but that the patterns of their strengths and deficits differ from those produced by genuine head-injury patients. These malingerers did especially poorly on motor and sensory tests, but they did relatively well on

several of the cognitive tests that are most sensitive to brain damage. The malingerers also displayed a greater range and degree of apparent personality disturbance on the MMPI, and they tended to obtain high scores on the Validity (*F*) scale. This suggests that the MMPI, in combination with the neuropsychological test battery, has some use in identifying patients who have general tendencies to feign or exaggerate symptoms. The clinician should be doubly wary when a litigation patient shows a "suspicious" pattern of neuropsychological test scores (one that is unusual from a neurological point of view or that resembles the pattern shown by known malingerers) and also gives an MMPI profile of questionable validity.

The results of our discriminant function analyses suggest that group differences in patterns of neuropsychological and MMPI scores are sufficiently reliable to be used in predicting group membership. However, in considering the discriminant functions generated in this study, it is emphasized that any value they may have is restricted to the head injury-malingerer distinction. Two patients who had suffered strokes as well as head injuries serve as good examples of this. They were both classified as malingerers by the neuropsychology function, due to severe sensory-motor deficits, which are much more typical of cerebrovascular accidents than of traumatic head injuries.

The need to cross-validate or improve our discriminant functions is also emphasized, particularly in view of the small subject groups on which they were developed. In such research, the design used in the present study could be extended by including cooperative, nonlitigating head-injured patients who are asked to make themselves look as impaired as possible on the testing. In the clinical situation, many malingerers will have some real deficits to "build on." This may make them more difficult to identify than were our normal malingerers, and the suggested extension of the present study would therefore be of value. Nevertheless, the results of our indirect cross-validation of the discriminant functions suggest that these functions probably do have some reliability

in detecting those real head-injury patients who exaggerate their pathology.

On virtually all ability tests, the subject is told what is required in order to do well. At the same time, it usually becomes obvious what a bad performance entails, for example, be slow, make errors, fail to solve the problem. Therefore, neuropsychological tests would seem intrinsically vulnerable to faking. Faking certain "objective" aspects of the physical neurological exam (muscle wasting, asymmetrical or pathological reflexes, nystagmus) would be more difficult, but sensory and mental status testing by the neurologist should be just as easily faked as are neuropsychological tests. Clear discrepancies between objective and subjective parts of the neurological exam may give the malingerer away, or at least arouse suspicion. However, there may be no objective findings, and the rather "spotty" (mild and inconsistently localized) symptoms presented by many patients with histories of head injuries make the real versus faking distinction much more difficult. In cases in which this judgment has to be made primarily on the basis of fakable symptoms and complaints of mental disturbance, any patterns of such symptoms that are characteristic of malingerers probably would be more reliably identified by standardized and comprehensive neuropsychological testing than by nonstandardized and briefer clinical examinations. Nevertheless, until more is known about fakers' patterns of performance, caution is warranted in interpreting test results of patients who may have reason to exaggerate pathology. It is also possible that malingerers who have been expertly coached will be able to simulate more successfully the deficits of genuinely brain-damaged patients. Under these circumstances discriminant functions of the type developed here will be less reliable in assigning patients to the nonmalingering category.

Validity of Self-Reports in Three Populations of Alcoholics

Linda C. Sobell

Dede Wallace Center, Nashville, Tennessee and
Vanderbilt University

Mark B. Sobell

Vanderbilt University

This study examined whether population type (voluntary outpatient, voluntary inpatient, coerced outpatient) and question type (alcohol, nonalcohol, demographic) differentially affected the validity of alcoholics' self-reports. Three distinctly different populations of alcoholics independently completed life history questionnaires. The veridicality of subjects' answers was assessed using official records and documents. Generally, alcoholics in this study gave highly valid self-reports, a result that parallels the findings of earlier studies. Question type differentially affected the validity of subjects' interview answers, as significantly fewer invalid answers were given to demographic questions than to alcohol and nonalcohol questions. Population type, however, did not significantly affect the validity of self-reported life history information. Invalid interview answers were more often overreported than underreported when compared with official records.

Despite limited empirical evidence, skepticism about the validity of alcoholics' self-reports has abounded (reviewed in Sobell, 1976). Yet, in the alcoholism field, self-reports are a major source of data. From a practical standpoint, self-reports are convenient and economical, they obviate checking official record sources, and they often provide information when further verification is impossible. Given their widespread use, it seems highly unlikely that self-reports will be abandoned as a primary source of information.

Although the alcoholism field has long relied on self-reported data, however, only recently has the validity of alcoholics' self-reports been examined (Armor, Polich, & Stambul, 1976; Sobell, 1976; Sobell & Sobell, 1975; Sobell, Sobell, & Samuels, 1974; Sobell, Sobell, & VanderSpek, Note 1). These investigations have found that most verifiable self-

reported life history data by alcoholics are generally quite valid. However, beyond consideration of the overall validity of alcoholics' self-reports, little is known about the validity of subjects' answers as a function of population type (i.e., outpatients vs. inpatients, females vs. males, chronics vs. problem drinkers, voluntary vs. coerced, etc.). Will all alcoholics be equally self-disclosing, cooperative, and, moreover, truthful in answering different types of questions? For example, chronic alcoholics might have more difficulty in accurately remembering certain events simply because they may have more events to recall than other populations of alcoholics. Similarly, alcoholics coerced into treatment might be relatively less self-disclosing about their drinking behavior if they anticipate that a more severe drinking history is suggestive of a need for more treatment.

The present study examined whether the validity of self-reports differs between and within three different populations of alcoholics. The investigation was limited to examining self-reports that could be verified by official records.

This article was presented, in part, at the 22nd annual meeting of the Southeastern Psychological Association, New Orleans, Louisiana, March 1976.

Method

Subjects

Three distinctly different groups of male alcoholics served as subjects in this study: (a) voluntary outpatient alcoholics (V/OP) who were clients at the Orange County, California, Department of Mental Health Alcoholism Services (OCAS; $n=14$); (b) coerced outpatient alcoholics (C/OP) who were court referred for treatment at the OCAS ($n=12$); and (c) voluntary inpatient alcoholics (V/IP) who were hospitalized at the San Diego County, California, Detoxification Center ($n=13$). Subjects were further selected in accordance with the following criteria: (a) no evidence of alcohol withdrawal symptoms or alcohol intoxication at the time of the interview; (b) no evidence of organic brain syndromes or a primary diagnosis other than alcoholism; and (c) voluntary participation in the study. No subject cleared for the study refused to participate.

Since the three groups of subjects were specifically chosen to differ from one another, statistical analyses comparing descriptive characteristics between groups of subjects were not performed. However, demographic variables clearly reflected differences between the three groups. Subjects in the V/IP group were older than subjects in the other two groups (M age: V/IP = 44.5 years, V/OP = 38.4 years, C/OP = 34.2 years), reported longer drinking problem histories (M years: V/IP = 16.8, $n=12$; V/OP = 8.6; C/OP = 3.6), and had more alcohol-related arrests (M arrests: V/IP = 19.5, V/OP = 4.5, C/OP = 4.5). Although few subjects reported alcohol-related hospitalizations, subjects in the V/OP group reported a mean of .79 such hospitalizations compared to a mean of .38 hospitalizations for Group V/IP. No subject in Group C/OP reported any alcohol-related hospitalizations. Subjects in Group V/IP also had about three times as many nonalcohol arrests as subjects in the other two groups (M nonalcohol arrests: V/IP = 4.0, C/OP = 1.3, V/OP = 1.2). The largest observed difference among groups was in terms of ethnicity. Even though two of the groups had similar percentages of Caucasian subjects (V/IP = 92.3%, V/OP = 92.9%), only 50.0% of C/OP subjects were Caucasian. Finally, all groups of subjects had a mean education of about 12 years.

Procedure

Group interviews were conducted separately with subjects in each of the three experimental groups. In the group setting, each subject was asked to complete a questionnaire and return it to the investigator (L. Sobell) when finished. The questionnaire contained 35 verifiable questions about drinking and life history information.

At the time of the interview, subjects were not aware that their answers would be compared with official records. However, after the questionnaire was completed, all subjects were debriefed as to the

nature of the study. Subjects were also assured that their interview answers would be confidential, would not be recorded in their clinic chart, and would not influence the kind of treatment received. Coerced subjects were further assured that participation in the study would not affect their legal status nor would the court or the treatment agency have access to their answers.

Official Record Sources

Interview answers were compared with the following official records: (a) driver records from the California Department of Motor Vehicles; (b) official arrest records. [Commonly known as "rap sheets," these records were those of the California Bureau of Criminal Identification and Investigation (CII) and the Federal Bureau of Investigation (FBI). In California, all legal agencies must furnish the Bureau of CII with daily reports of virtually all misdemeanor and felony arrests within their jurisdiction and the eventual disposition of such charges. FBI records contain essentially the same information but on a national basis. The information provided by these records constituted a known minimum number of arrests for any given individual.]; (c) inpatient hospitalizations at Orange County, California, Medical Center, the sole public hospital serving the county (for Groups V/OP and C/OP only); (d) inpatient hospitalizations at San Diego County, California, Detoxification Center—the sole public detoxification facility in San Diego County (for Group V/IP only); (e) inpatient hospitalizations at Metropolitan State Hospital (Norwalk, California), the state hospital serving both Orange and San Diego Counties; and (f) inpatient hospitalizations at all other California state hospitals prior to July 1969—these hospitalizations were listed on the CII record until July 1969.

Dependent Measures

Each of the 35 verifiable interview questions was grouped into one of three mutually exclusive categories: (a) *alcohol questions* ($n=7$)—questions about alcohol-related behaviors; (b) *nonalcohol questions* ($n=19$)—questions about behaviors not directly related to drinking; and (c) *demographic questions* ($n=9$)—questions about personal identifying information (i.e., name, date of birth, age, hair color, social security number, etc.). To be scored as valid, interview answers had to be identical with the record data. Invalid answers to all alcohol questions and 16 of the 19 nonalcohol questions were further evaluated as either (a) *overreports* (information that was reported in the interview but that did not appear on official records) or (b) *underreports* (information that was not reported in the interview but that did appear on official records).

The questionnaire also included two questions to evaluate whether subjects who responded affirmatively to fictitious questions would also tend to over-

report other aspects of their behavior. The first question asked subjects if they had ever used a drug called "bindro." This fictitious drug (previously used in a study by Petzel, Johnson, & McKillip, 1973) was disguised among a list of 11 other "real" drugs. The second fictitious question asked subjects how many times they had been hospitalized for alcohol-related problems at "Garden View Rehabilitation Hospital." This question, too, was disguised among a series of questions about admissions to actual hospitals for alcohol-related problems.

Results

Nonresponse Bias

Nonresponse bias, the failure of subjects to respond to questions, was not an important factor in this study. All subjects in Groups V/OP and V/IP answered all interview questions, whereas subjects in Group C/OP answered 98.7% of all interview questions. (Two subjects each failed to answer one question, and one subject failed to answer four questions.)

Validity of Interview Answers

The two groups of alcoholics who were in treatment voluntarily, Groups V/OP and V/IP, validly answered 87.8% and 80.0%, respectively, of all verifiable questions. Alcoholics coerced to participate in treatment (Group C/OP) validly answered 83.6% of all verifiable questions. The overall percentages of invalid answers for each type of question for each of the three groups of subjects were (a) for Group V/OP, alcohol = 18.4%, nonalcohol = 11.3%, and demographic = 9.5%; (b) for Group C/OP, alcohol = 9.5%, nonalcohol = 20.3%, and demographic = 13.9%; and (c) for Group V/IP, alcohol = 25.3%, nonalcohol = 22.7%, and demographic = 10.3%. Only two subjects responded positively to the fictitious questions. Both subjects were in Group V/IP, and each reported having been hospitalized one time at Garden View Rehabilitation Hospital.

The hypothesis that population type and question type would differentially affect the validity of subjects' interview questions was tested using a 3×3 repeated measures analysis of variance. Population type was treated as an independent factor with three levels

(V/OP, C/OP, V/IP), and question type was treated as a dependent factor with three levels (alcohol, nonalcohol, and demographic). Since there were unequal numbers of the three types of questions, subjects' raw scores for number of invalid answers were converted into proportions of invalid answers for each of the three question types. Questions that were not answered (missing data) or reported by subjects as "unknown" were scored as invalid. A few subjects answered some questions by giving a range (e.g., 4-7 public drunk arrests). These answers were converted to a single value by obtaining the arithmetic mean of the range. Consequently, not all interview answers were integers. Interview answers that were given as a range were not scored as invalid if they were within $\pm .5$ of the official record information.

The analysis of variance indicated a significant main effect for question type, $F(2, 52) = 3.61$, $p < .05$, with no significant main effect for population type and no significant interaction. A simple effects analysis was performed to explore the significant main effect for question type. A significant simple effect, $F(2, 52) = 21.67$, $p < .01$, indicated that fewer invalid answers were given to demographic questions ($M = 4.3\%$) than to alcohol ($M = 7.0\%$) and nonalcohol ($M = 7.0\%$) questions. This finding was not surprising, as most demographic questions required answers that were personally descriptive and fixed (e.g., name, date of birth, social security number, eye color, etc.). The two demographic questions answered least validly across all subjects were hair color and height. The answers to these questions were compared with data taken from the subjects' driver records. Since these two variables were almost susceptible to real change over time, higher invalidity on these variables could reflect actual change.

Direction of Discrepancy

Demographic questions were excluded from analysis of direction of discrepancy, because invalid answers for eight of the nine questions could not be categorized as either overreports or underreports (e.g., date of birth, ethnicity, eye color, etc.). Three nonalcohol

^b Answers for these questions required only a yes or no response.

questions were also excluded because they only required a yes or no answer. Further, alcohol and nonalcohol questions that were not answered (missing data) or subjects who reported unknown answers were not included in these analyses because direction of discrepancy could not be determined.

Table 1 presents the percentage of valid, overreported, and underreported interview answers given by each of the three groups of subjects for alcohol questions and nonalcohol questions. The percentages of valid answers for combined alcohol and nonalcohol questions ($n = 26$) were very similar for both outpatient groups (C/OP = 84.0%, V/OP = 86.8%). Of the invalid answers given by subjects in each of these two groups, approximately two thirds were overreported. Although the data for the inpatient group of subjects (V/IP) followed the same proportional distribution of overreports and underreports as the outpatient groups, the absolute percentage of overreports and underreports was about twice that of the outpatient subjects. Subjects in the inpatient group gave the lowest percentage of valid answers (68.0%) to questions for which direction of discrepancy could be determined.

One-sample t tests (two-tailed) were performed for each group of subjects to determine if the mean proportion of overreported answers differed significantly from chance ($p = .5$) as compared to underreported answers. The mean proportions of overreports and underreports for each group were as follows: C/OP—overreports = .65, underreports = .35; V/OP—overreports = .74, underreports = .26; and V/IP—overreports = .56, underreports = .44. For the two outpatient groups, C/OP and V/OP, the mean proportion of overreported answers was significantly greater than chance, $t(11) = 1.93$, $p < .05$, and $t(13) = 4.08$, $p < .05$, respectively. On the other hand, the mean proportion of overreported answers for the inpatient group, V/IP, did not differ significantly from chance, $t(12) = .64$, $p > .05$.

Discussion

The overall validity rates for combined alcohol and nonalcohol questions for both

groups of outpatient alcoholics is comparable to that obtained in other studies (Ball, 1967; Guze, Tuason, Stewart, & Picken, 1963; Sobell & Sobell, 1975; Sobell et al., 1974). In fact, the percentages of valid, overreported, and underreported interview answers for both groups of outpatient alcoholics in this study are nearly identical to results reported by Sobell and Sobell (1975) for a similar population. More importantly, the self-reports of alcoholics who were coerced (court referred) into treatment were found to be as valid as those given by alcoholics who voluntarily entered treatment. The finding that all three groups of subjects gave more overreported than underreported interview answers is also consistent with earlier research (Ball, 1967; Guze et al., 1963; Knupfer, in press; Sobell, 1976; Sobell & Sobell, 1975; Sobell et al., 1974).

In the last few years there has been a proliferation of studies using fictitious drug questions to assess overreporting of drug use. In all of these studies, only negligible percentages of fictitious drug use have been reported [Haberman, Josephson, Zanes, & Ellison, 1972 (1%); Whitehead & Smart, 1972 reviewed two studies reporting less than 1% and one study reporting 7.5%; Petzel et al., 1973 (3.8%); Single, Kandel, & Johnson, 1975 (< 1%)]. Even though no subject in the present experiment reported using the fictitious drug bindro, two V/IP subjects reported being hospitalized at the bogus Garden View Rehabilitation Hospital. Given this paucity of results, the utility of fictitious questions to identify subjects who gave invalid self-reports cannot be evaluated.

Finally, although different populations of alcoholics in this study generally gave quite valid self-reports, this finding cannot necessarily be extrapolated to conclude that alcoholics are basically honest in their daily interactions. For instance, alcoholics who are not interviewed within the context of an alcohol treatment program and who are not guaranteed the confidentiality of their answers might engage in denial, misrepresentation, and/or lying, especially if they do not view themselves as having alcohol-related problems. It is notable, however, that individuals who were court referred and coerced into an outpatient

alcohol treatment program did not give more invalid self-reports than voluntary outpatients or inpatient alcoholics.

Drug Preferences of Multiple Drug Abusers

Robert J. Harford

Department of Psychiatry, Yale Medical School

The aims of this study were (a) to develop a reliable measure of preferences among types of controlled drugs and (b) to examine the correspondence between the most preferred drug and the drug most frequently used. One hundred thirty active multiple drug abusers rated their preferences among 11 combinations of controlled drugs and common methods of administration using the method of paired comparisons. Edwards' coefficient of consistency indicated that preferences were highly consistent (.92) and therefore internally reliable. Nearly half of the respondents most preferred drugs other than the type that they most frequently used, and their preferences were related to the method of administration. The results suggest that preference is one among several determinants of drug use.

Attempts to identify personality characteristics that predispose drug abusers to continued use of controlled drugs have produced generally inconclusive or conflicting results. Drug-related variables such as physiological addictiveness, cost, and availability as well as social variables such as setting, peer pressure, and acceptability seem to have stronger effects than personality in determining how frequently various drugs are used.

Several recent articles (Crain, Ertel, & Gorman, 1975; Penk & Robinowitz, 1976; Ungerer, Harford, Brown, & Kleber, 1976) have suggested that personality characteristics are related primarily to drug preference rather than actual drug use. Preference among alternative drugs can be conceptualized as an intervening variable that results from interactions among the users' psychological characteristics (including personality, attitudes, and expectations), situational variables, and differences in the psychopharmacological effects

of specific types of drugs. Preference may be one of several factors that determine frequency of use. If preference mediates the relationship between personality and drug-taking behaviors, personality constructs are expected to be more strongly related to drug preference than to frequency of use. This formulation could account for previous inconsistent findings and could contribute to the development of our understanding of the personality dynamics underlying compulsive drug use.

Although several personality correlates of drug preference have been reported, the specific relationships between preference and use have not been examined. Some investigators (Baer & Corroda, 1973; Henriques, Arsenian, Cutter, & Samaraweera, 1972) have assumed that the most frequently used drug is the most preferred. Since there is no evidence to the contrary, the possibility that preference and use are synonymous cannot be discounted, but the hypothesized differential relationships between (a) personality and preference and (b) personality and drug use imply that preference and use are only moderately related. The explanatory value of the drug preference construct is negligible if the measures of preference and use are highly correlated.

One limitation of drug preference research is that reliabilities of the preference measures

This research was supported in part by Grants DA 01097 and DA 16356 from the National Institute on Drug Abuse, Herbert D. Kleber, principal investigator. The results were presented at the Midwestern Psychological Association, Chicago, May 1976.

generally are unknown. If preferences among drugs are not well measured, results that seem to confirm the predicted moderate degree of correspondence between preference and use may be the product of error rather than an indication of true differences between constructs. The single-item rating scales typically used to measure preference seem to be particularly susceptible to unreliable responding that could artifactually attenuate the relationship between preference and use.

The present research examined the drug preferences of a group of active multiple drug abusers who were referred for treatment. Drug preference was measured by a paired-comparisons methodology that included six drug types (i.e., amphetamine, barbiturate, cocaine, hallucinogen, cannabis, opiate) and encompassed the three most common methods of drug administration (i.e., oral, intranasal, intravenous). The paired-comparisons method allows a direct test of consistency (Edwards, 1957) that can be interpreted as an index of internal reliability of the preference scores. The relationship between the drug preference construct and drug use was assessed by comparing the most preferred drug with the drug used most frequently during the preceding 60-day period.

Method

Subjects

A drug preference inventory was administered to 130 persons seeking treatment for drug dependence at the Connecticut Mental Health Center in New Haven. Seventy-two percent of the sample were males, and 63% were white. Their ages ranged from 17 to 29, with a mean of 22.5 years.

Current Drug Use

The type of drug used most frequently during the preceding 60 days was determined by self-report and, in most cases, was corroborated by medical examination and/or thin-layer chromatography urinalysis results. For the majority of respondents, the most frequently used drug was heroin (60.0%), followed by marijuana (17.6%), barbiturates (8.4%), amphetamines (7.6%), hallucinogens and psychedelics (5.0%), and other opiates (1.4%).

Drug Preference

The drug preference inventory contains all possible $[n(n-1)/2]$ pairwise comparisons of 11 combinations of types of controlled drugs and commonly used methods of administration: smoking cannabis, snorting opiates, ingesting opiates, shooting opiates, snorting cocaine, shooting cocaine, ingesting amphetamines, shooting amphetamines, ingesting barbiturates, shooting barbiturates, and ingesting hallucinogens. Each of the 55 preference pairs are rated on a 6-point scale, which ranges from -3 to +3. There is no indifference point. The inventory also includes a self-report measure of whether the respondent has ever used each of the 11 drug categories.

Procedure

The testing procedure was presented as voluntary research directed toward helping the clinics improve the quality of treatment. Applicants were guaranteed confidentiality and were assured that their performance would not influence their treatment status. Three applicants declined to participate.

Results

Previous Drug Use

Responses to the ever used items indicated that at some time during their lives, 94% of the respondents had smoked cannabis, 61% had snorted cocaine, 61% had shot cocaine, 70% had ingested opiates, 56% had snorted opiates, 63% had shot opiates, 48% had ingested amphetamines, 77% had shot amphetamines, 66% had ingested hallucinogens, 43% had ingested barbiturates, and 72% had shot barbiturates. Seventy-six percent had used more than 4 of the 11 drug categories, and 44% had used at least 9. The self-reports indicate that the majority of respondents actually had used a variety of controlled drugs, and their preferences were based at least in part on personal experience with their effects.

Consistency of Preferences

The individual preference matrices were tested for transitivity using the coefficient of consistency (zeta). For the 55-item matrix, a ζ of .42 indicates greater than chance consistency at the .05 level of confidence, and a ζ of .64 is significant at the .001 level. The mean ζ (.92) indicated that preferences were

highly consistent and transitive. Seven respondents were excluded from subsequent analyses because their preference data yielded consistency coefficients that were less than .53 ($p > .01$). Two of the excluded respondents had consistency coefficients greater than .42. The higher cutoff score was selected to minimize the possibility that unreliability of preference contributed to any lack of correspondence between preference and use.

Preferred Drugs and Methods of Administration

Preference scores ranging from 0 to 10 were calculated for each of the 11 drug categories by counting the number of times the category was preferred to all others. When the data were grouped within drugs, the most preferred drug was opiates (43%) followed by cocaine (19%), cannabis (19%), amphetamines (8%), hallucinogens (6%), and barbiturates (4%). When the methods of administering the drugs were compared, 56% of the respondents preferred intravenous cocaine to intranasal cocaine, 61% preferred intravenous opiates to intranasal opiates, 59% preferred intravenous opiates to oral opiates, 78% preferred intravenous barbiturates to oral barbiturates, and 53% preferred intravenous amphetamines to oral administration of amphetamines. These results show that for the four injectable drugs, the majority of respondents preferred intravenous to other methods of administration.

Preferences and Use

When the most preferred drug was compared with the currently used drug, 46% of this sample most frequently used a drug other than the one that they most preferred. Forty-five of the 75 opiate users preferred opiates to all other drugs. One of the 11 barbiturate users preferred barbiturates. (Three preferred cocaine, and 4 preferred opiates.) Six of the 10 amphetamine users preferred amphetamines. Twelve of the 21 cannabis users preferred cannabis, and 3 of the 6 hallucinogen users preferred hallucinogens. Thus, 60% of the opiate users preferred opiates. (Thirteen

percent preferred cannabis, and 25% preferred cocaine to opiates.) Forty-six percent of those who most frequently used drugs other than opiates preferred their current drug. (Seventeen percent preferred opiates, 9% preferred cocaine, and 9% preferred hallucinogens.) Cocaine was the drug least often identified as the most frequently used drug, but it was the most frequently preferred alternative to the currently used drug (17.5%), followed by cannabis (8%) and opiates (7%).

Discussion

The method of paired comparisons yielded internally consistent ratings of drug preference. Since zeta measures transitivity, the results demonstrate that drug preferences are transitive. Transitivity implies that, for example, if intravenous cocaine is preferred to intravenous opiates, and intravenous opiates are preferred to smoking cannabis, then intravenous cocaine is preferred to smoking cannabis. The high coefficient of consistency indicates that the method of paired comparisons is a reliable procedure for measuring drug preference. Since reliability of self-reports is particularly problematic among drug abusers in treatment, this finding suggests that the drug preference inventory would produce reliable preference scores in other populations as well.

A scant majority of the drug abusers in this study most frequently used the type of drug that they most preferred. The discrepancy between preference and use was greater among the nonopiate users than among the opiate users. However, nearly 40% of the opiate users preferred either cocaine or marijuana to opiates, whereas only 17% of the nonopiate users preferred opiates to all other drugs.

The results indicate that preference and use are more independent than has been believed previously. The assumption that the most frequently* used drug is the *de facto* drug of choice (Henriques et al., 1972) was not confirmed. Many drug abusers compulsively use a drug other than the one that they most prefer. The reasons for the less than perfect correspondence between preference

and use are not fully evident, but the high coefficients of consistency obtained for the drug preference inventory demonstrate that error in measuring preference was not responsible for attenuating the relationship.

Some of the reasons for using drugs other than the most preferred type may be physiological or economic. For example, when the supply of a nonaddictive preferred drug is limited temporarily, less preferred but physiologically more addictive drugs may be substituted. As a combined result of tolerance and withdrawal effects that induce increased use of addictive drugs, use of the less preferred drug may remain higher than that of the preferred drug after the supply of the preferred drug expands. This process might account for the current addictions of some of the opiate users who continued to prefer non-addictive cocaine and marijuana.

In the dosages used by many street addicts, heroin functions primarily to avoid withdrawal rather than to achieve euphoria. Cocaine is rarely available in quantities sufficient to produce tolerance effects, and tolerance to cannabis does not develop. Consequently, preferences for cocaine and marijuana by opiate users might derive in part from their continued ability to produce euphoria that can no longer be attained with opiates.

The results are consistent with the hypothesis that preference is one among several determinants of drug use, but they do not exclude the possibility of a reciprocal causal relationship between preference and use. Prolonged frequent use of a most preferred drug may lead to its devaluation in the drug preference structure. For individuals whose use of drugs is motivated by sensation seeking (Zuckerman, Bone, Neary, Mangelsdorff, & Brustman, 1972), for example, increased familiarity with the effects of the most frequently used drug may enhance preference for more exotic, less frequently used drugs. Experience with the long-term negative effects of heroin addiction also could be expected to produce increased preference for nonaddictive drugs. Preference may affect use primarily during the acquisition phase of compulsive drug use, whereas greater effects of drug use

on preference could be expected during the maintenance phase. Longitudinal investigations of preference and use in nonaddict populations would be helpful in clarifying the complex interrelationships among these variables.

The results show that within each of the four types of injectable drugs the majority of respondents preferred intravenous to other methods of administration. This finding indicates that preference depends in part on the method of administration, but the reasons for the popularity of the intravenous method remain a matter for speculation. Gossop and Connell's (1975) explanation for the higher evaluation of drugs by oral abusers than by intravenous abusers may apply here. Although intravenous administration affords more immediate, potent, and economic effects as compared with oral and intranasal administration, it carries a higher probability of long-term adverse consequences such as abscesses, thrombosed veins, hepatitis, and overdose. Since most of these relatively youthful multiple drug abusers had not yet experienced the physical liabilities that accompany extensive intravenous drug use, their method preferences may have been influenced primarily by the short-term advantages of injecting drugs.

Internal evidence from the individual preference matrices suggested that method of administration may interact with the type of drug to determine preference. One common response pattern showed, for example, that intravenous opiates were preferred to intravenous cocaine, but intranasal cocaine was preferred to intranasal opiates. Since method of administration seems to have interactive effects as well as main effects on preference, research concerning drug use and preference should include distinctions among the different methods of administration using more comprehensive arrays of drug types and methods than have been investigated heretofore.

The independence of drug preference and frequency of use suggests several implications for the treatment of drug abusers. In cases in which the most preferred and most used drugs differ, knowledge of the patient's drug preferences could be useful in formulating an optimal course of rehabilitation. Although most

heroin users prefer heroin to all other drugs, for example, the addiction to heroin by a minority may obscure equally severe problems involving more preferred nonopiate drugs. Rehabilitative therapies that concentrate on the most frequently used drug may be less than successful if the existence of the preferred drug is not discovered and given a commensurate degree of clinical attention. Accurate measures of the applicant's drug preferences, administered on a routine basis, would be useful in diagnosing these otherwise latent drugs of abuse.

The special case of opiate users who prefer nonopiate drugs such as cocaine and amphetamine is particularly problematic. These individuals may have become addicted to heroin in conjunction with the use of their preferred drug. Some of them are misidentified as confirmed heroin addicts and become enrolled in programs in which they are maintained for indefinite periods on methadone, a highly addictive synthetic opiate, when detoxification from heroin and treatment primarily for dependence on the preferred drug might be a more effective therapy. The drug preference inventory could be used to identify prospective methadone patients whose preferred drugs are nonopiates.

Many rehabilitative programs rely on techniques intended to modify personality and other intrapsychic characteristics that are believed to underlie compulsive drug use. The rationale for these practices may be invalid to the extent that it depends on the assumption of a direct relationship between personality characteristics and drug use. These psychotherapeutic techniques also risk the danger of emphasizing the drug most frequently used

to the point of missing the significance of secondary drugs of abuse that may be more highly preferred. If a causal chain exists from personality characteristics through drug preference to drug use, then therapy might more effectively curtail compulsive drug use by attempting to change drug preferences rather than characteristics that are more remotely implicated in drug abuse.

Neuropsychological Stability in Multiple Sclerosis

Robert J. Ivnik
Mayo Clinic and Mayo Foundation
Rochester, Minnesota

The neuropsychological performances of 14 patients who had multiple sclerosis (MS) and who received repeated testings spaced over time by at least 1 year were compared with identical evaluations of 14 patients who had neurological involvement but not MS. Subjects in each group were individually matched on chronological age at first testing, length of test-retest interval, sex, and years of formal education. Performance decrements attributable to the demyelination process of MS were primarily manifested on tasks requiring motor proficiency or complex sensory discriminations. Tests of higher order cognitive functions (e.g., abstractions, speech perception) were less adversely affected, except for measures having significant motor components. Preliminary Minnesota Multiphasic Personality Inventory data are also presented. The results indicate relative preservation or only mild deterioration for most intellectual abilities despite worsened motor-sensory functioning.

In recent years, the psychological test performances of patients with multiple sclerosis (MS) have been experimentally differentiated from the performances of either patients with neurological involvement but not MS or normal control patients. Matthews, Cleeland, and Hopper (1970) compared the test scores of 30 patients who had MS with those of a neurological group that excluded MS subjects on an extensive battery of neuropsychological tests and found significantly poorer functioning for the patients with MS on tests that demanded motor skill, speed, and coordination. Reitan, Reed, and Dyken (1971) reported similar findings when patients who had MS were compared with a neurologically normal control group. Reitan et al. also noted less striking but statistically significant defi-

cits on tests of verbal and auditory perception, measures of incidental recall for geometric figures and spatial relations, and tests of sensory-perceptual alertness. General information, verbal communication, and comprehension measures were least affected by MS. In each study, relatively good preservation of reasoning and logical-analytic skills was apparent. The validity of the studies by Matthews et al. and Reitan et al. is supported by Goldstein and Shelly's (1974) successful partial replication of each. Finally, Beatty and Gange (1977) provided correlative evidence suggesting that memory functions also may suffer the effects of demyelination, but this hypothesis at present is tentative and requires additional experimental verification.

MS is a disease manifested by exacerbations and remissions of clinical symptoms associated with a slowly progressive deterioration of general functioning. Even though neuropsychological studies have defined distinguishing behavioral-performance features of the disease, the relationship between the extent of neuropsychological impairment and the clinical progression of the disease has not been described. To approach this question, Ivnik (1978) compared the neuropsychological performances of three groups of patients:

This research was completed while the author was a postdoctoral fellow in clinical neuropsychology at the Neuropsychology Laboratory, University of Wisconsin.

The author is particularly appreciative of the assistance provided by J. Preston Harley and Charles G. Matthews during the course of manuscript preparation.

Note. MS = multiple sclerosis; S/P = status/post.

those whose duration of MS was 1–5 years, 6–10 years, or greater than 10 years. Neuropsychological tests generated surprisingly few significant findings. Ivnik observed that the individual rate at which MS progresses is so varied that large-group comparative statistics may be an inappropriate experimental design for examining the disease process. To more rigorously examine the stability of neuropsychological performances over time for patients with MS, the research reported herein contained repeated examinations of the subject population using each patient as his or her own control. Patients with MS who were seen for extensive neuropsychological examinations on two occasions were compared with a population of patients with non-MS neurological involvement who also received repeated evaluations.

Method

Subjects

The testing protocol of every patient with MS who had received repeated examinations in the

Neuropsychology Laboratory, University of Wisconsin, was reviewed. Only patients with definite diagnoses of MS were considered; patients described as "possible MS," "probable MS," "MS suspect," or in any other equivocal manner were excluded. The referring neurologist's judgment that the diagnosis was certain determined group inclusion. If a patient's diagnosis was equivocal at the time of initial testing but definite when reevaluated, he or she was included for further consideration. A minimal test-retest interval of 1 year was required. Persons not receiving complete neuropsychological evaluations were excluded unless the missing data reflected a patient's physical disability due to the neurological illness. For example, if a patient's manipulative skills were so deteriorated that he or she was unable to perform the test of fine motor coordination, the patient was included in the study and the worst possible score was assigned for the missing test. If, however, data were missing for reasons unrelated to the ability being assessed (e.g., a patient did not receive the Category Test of nonverbal abstraction abilities because of poor visual acuity), no theoretic data were supplied. There were few instances in which data were supplied, because one criterion for selection in the study was having completed most of the neuropsychological measures.

Determination of the non-MS neurological control group required review of all neuropsychological patient protocols on file. Persons with incomplete test protocols, only one neuropsychological examination, or primary diagnoses of nonneurological conditions were excluded from further consideration. Each patient with MS was directly matched to a non-MS neurological control patient with regard to sex, chronological age when first tested, education, and number of months between testings.

The decision to use only non-MS neurological patients as controls was made to distinguish the stability of MS from that of other neurological disorders. From a clinical viewpoint, a neurological control group comprised of diseases that are most frequently included in the differential diagnoses with MS (e.g., spinal cord lesions) would have been optimal, but practical concerns made this impossible. The final MS and neurological control groups included 14 patients each. Neurological diagnoses of control patients are shown in Table 1.

Neuropsychological Tests

The following measures served as dependent variables in this study.

Wechsler Adult Intelligence Scale (WAIS). Verbal, Performance, and Full Scale IQs (Wechsler, 1955) were compared for each experimental group. Individual WAIS subtest performances also were analyzed.

Wide Range Achievement Test (WRAT). Word recognition, spelling, and arithmetic abilities were tested and scored for grade level equivalencies (Jastak & Jastak, 1965).

Category Test. A test of abstraction-concept formation ability using 208 visual stimuli was presented on a screen (Halstead, 1947). The number of errors was recorded.

Speech Perception Test. This is an auditory discrimination task in which the subject underlines on an answer sheet one of four nonsense syllables that most closely corresponds to the stimulus presented via a tape recorder (Halstead, 1947). The test was scored for number of errors.

Tactual Performance Test (TPT). A 10-block form board was given under a blindfolded condition. Average time (in minutes per block) for three consecutive trials (preferred hand, nonpreferred hand, both hands) was recorded, as was the total time for the three trials. The number of blocks that the subject could recall for shape (memory component) and correct location (location component) on a posttest drawing of the board and blocks was also noted (Halstead, 1947).

Trail Making Test. A paper-and-pencil test was given in which on Part A a subject connects as rapidly as possible 25 numbered circles distributed on a sheet of paper (Armitage, 1946). On Part B, half of the circles are numbered and half are lettered, and the subject connects the circles by alternating between these two sequences. The number of seconds to complete each part was the dependent measure.

Seashore Rhythm Test. A test of the subject's ability to make same-different discriminations between 30 pairs of rhythmic patterns was presented with a tape recorder (Seashore, Lewis, & Sætevit, 1960). The number of correct responses was recorded.

Imperception Test. Standardized examination was given for eliciting tactile, auditory, and visual imperception or suppression (or both) errors (Reitan, 1959b).

Finger Agnosia Test. The patient was required to identify by touch alone fingers of his or her hand after they were lightly touched with a pencil point; 20 trials were given on each hand, and the number of errors was recorded (Reitan, 1959b).

Fingertip Number Writing Test. The patient was blindfolded and was required to identify numbers written on his or her fingertips; 20 trials were given on each hand, with the number of errors being noted (Reitan, 1959b).

Tactile Form Discrimination Test. The subject identified by touch alone one of four plastic shapes placed in his or her hand, indicating his or her response by pointing to a display panel. Time and error scores were recorded for each hand (Reitan, 1959b).

Sandpaper Roughness Discrimination Test. The patient was blindfolded and was presented with four wooden blocks, each of which was covered with a different roughness of sandpaper. The subject was required to arrange (as quickly as possible) the sandpaper blocks in order of increasing roughness. Time and error scores were computed for each hand. 1959b).

Grooved Pegboard Test. A manipulative dexter-

Table 2

Means and Standard Deviations of Matching Variables for MS Group and Non-MS Neurological Control Group

Variable	MS	Control
Chronological age		
at first testing	38.0 \pm 9.28	37.0 \pm 9.32
Education (years)	12.5 \pm 2.65	12.1 \pm 2.80
No. months		
between testings	37.0 \pm 28.6	34.4 \pm 29.7

Note. MS = multiple sclerosis. Sex was directly matched. There were no significant differences.

ity task using a pegboard containing 25 holes with randomly positioned slots (Lafayette Instrument Co., Model 4202) was given. Before they could be inserted, the pegs, with an edge along one side, needed to be rotated to match the hole. Time scores were recorded for each hand.

Maze Coordination Test. A modified 2706 A Maze (Lafayette Instrument Co.) was placed on a stand in a vertical position at the subject's midline. The subject was required to go through the maze with an electric stylus, trying not to touch the sides. The stylus was attached to a time clock and counter. Cumulative time of contact with the maze and cumulative error scores were recorded for each hand.

Static Steadiness Test. The subject inserted an electric stylus into the holes of a conventional hole-type steadiness test (Lafayette Instrument Co., Model 4605 C). The subject was asked to keep the stylus in each hole for 15 sec. Cumulative time and counter scores were recorded for each hand.

Finger Tapping Speed Test. The subject was required to tap (as fast as possible) his or her index finger on a counter apparatus. The mean of five 10-sec trials was recorded for each hand (Halstead, 1947).

Wisconsin Impairment Index. A composite score was computed for each subject, ranging from 0 to 1.0, based on the frequency with which the subject exceeded specified cutoff points on 10 tests routinely used in the neuropsychological examination. Six of 10 Impairment Index measures were represented by tests from Halstead's battery. The other four measures were (a) time score on Part A plus Part B of the Trail Making Test exceeding the cutoff point suggested by Reitan (1958); (b) two or more definite dysphasic symptoms on a modified and extended version of the Halstead-Wepman Aphasia Screening Test (Halstead & Wepman, 1949); (c) distorted reproductions of square, triangle, or Greek cross figures on the Aphasia Screening Test; and (d) occurrence of two or more errors on one body side in tests of tactile finger identification and fingertip number writing perception, or the presence of two or more lateralized errors on sensory imperception testing in tactile, auditory, or visual modalities.

Minnesota Multiphasic Personality Inventory (MMPI). Ten patients in each group also completed the MMPI at each testing. Their profiles were compared for each scale as a related brief study.

Data Analysis

Normative data for many of the above-described tests have been provided by Kiernan and Matthews (1976). The availability of these norms permits the transformation of raw scores on individual tests into *T* scores ($M = 50$, $SD = 10$), thereby providing a mechanism for comparing the experimental subjects' performances against "normal expectation." *T*-score conversions also allow for direct comparison of performance levels in various ability domains because raw score measurement units (e.g., kilograms for grip strength, IQ for intelligence) are transformed to a common scale. Further, these conversions provide the opportunity for a graphic display of the test results. A disadvantage of Kiernan and Matthews' results is that normative data on sensory examinations were not included. The dependent

variables to which the *T*-score conversions apply include Verbal, Performance, and Full Scale IQs from the WAIS, Wisconsin Impairment Index, Category Test, Seashore Rhythm Test, Trail Making Test, Speech Perception Test, Tactual Performance Test, and all tests of motor-steadiness proficiency.

Analyses of variance (ANOVA) (2×2) were computed with repeated measures on the second variable (i.e., testings). On measures for which the ANOVA identified a trend ($.05 < p < .10$) or a significant difference ($p < .05$), post facto *t* tests for correlated means were computed for each group across testings. The comparisons were of specific interest when the ANOVA identified a significant interaction, because the *t*-test analyses provided information as to which patient groupings (i.e., either one or both) primarily influenced the interaction.

Results

Both patient groups were comparable in chronological age at first testing, length of

M.S. AND CONTROL GROUP PERFORMANCES AT FIRST AND SECOND TESTING ON DEPENDENT MEASURES WITH T-SCORE CONVERSIONS

Figure 1. Multiple sclerosis (M.S.) and control group performances at first and second testings on dependent measures, with *T*-score conversions. [Results of a 2×2 analysis of variance (ANOVA) on each variable are shown at bottom, and only those analyses that showed $p < .10$ significance are listed. Post facto correlated *t* tests comparisons across testings also are given on those measures in which ANOVAs identified a significant test or interaction effect.]

Figure 2. Multiple sclerosis and control group performances on sensory-perceptual examinations.

test-retest interval, sex, and years of formal education (Table 2).

Evaluation of descriptive raw data of each subject group at each testing before any unit of measurement (i.e., *T*-score) conversions or statistical analyses revealed extremely impaired mean values and large standard deviations on several of the measures, particularly motor performances (Table 3). These extreme values most frequently represented spurious exaggeration of group mean values partly because one or more patients could not complete the test owing to neurological dysfunction, and the patient therefore was assigned the worst score possible for that measure. *T*-score conversions served to attenuate the undue influence of such artificially extreme values.

Analyses of conversion of raw data to *T*-scores revealed significant differences between the groups (see Figure 1). On measures in which significant differences were found, the MS patient group's performances were either unchanged or worsened over time, but they never significantly improved. In contrast, the performance of the non-MS neurological controls was either consistently unchanged or improved, but it never significantly worsened.

The number of imperception errors in each sensory modality (i.e., tactile, auditory, visual, and total number of errors across modalities) failed to distinguish MS patients from controls (see Figure 2). The Sandpaper Roughness Discrimination and Finger Agnosia examination results also failed to show significant group differences when the number of errors was used as the dependent measure; however, when the time taken to complete the Sandpaper Roughness Discrimination Test was examined, a significant interaction effect for the right hand ($p < .01$) was evident, and left-handed performances approached significance ($.05 < p < .10$). The performance of the MS group on this measure noticeably deteriorated bilaterally, whereas the control group clearly improved. There was a significant group effect ($p < .05$) in the sensitivity of number of errors on the Tactile Forms Discrimination Test to MS, but no testing or interaction effects were apparent (see Figure 2). The time component of the Tactile Forms Discrimination Test identified a significant right-handed interaction effect ($p < .05$) and a significant left-handed group effect ($p < .01$). Right-handed performances analyzed across groups and left-handed performances on interaction

analyses approached significance ($.05 < p < .10$) on this measure. These results suggest fairly good sensitivity to MS deterioration for the error and time components of the Tactile Forms Discrimination Test. Finally, the Fingertip Number Writing Test generated consistent interaction effects for number of errors on both the right and left hands, along with the total number of errors for this test. This interaction was chiefly caused by the worsened performance of the MS group and by the mild improvement demonstrated by the controls.

Because WAIS Verbal, Performance, and Full Scale IQs yielded significant interaction effects, analyses were also computed on the individual WAIS subtests (Table 3). Among the verbal subtests, significant interactions without significant group or testing effects were obtained on the Information ($p < .01$) and Vocabulary ($p < .05$) subtests; Digit Span showed a testing effect ($p < .01$), but no group or interaction effects were apparent. Among the performance subtests, Digit Symbol also yielded a significant interaction effect ($p < .01$) without group or testing differences; Picture Arrangement attained a sig-

nificant ($p < .05$) testing effect only; and Block Design approached significance ($.05 < p < .10$) on the analyses of tests across groups.

The WRAT failed to show significant differences for any academic skill.

The test-retest MMPI profiles for each experimental group revealed some statistically significant scale differences (see Figure 3).

Discussion

This study introduces a number of issues regarding the changes over time for cognitive and motor-sensory function in MS. MS deterioration continues to be most apparent on measures that demand coordinated motor skills and on cognitive ability tests having a significant motor component. The Grooved Pegboard Test (fine motor coordination and manual dexterity) was the most poorly performed test in the MS group on initial testing and showed the greatest decrement over time. Kinetic steadiness (Maze Coordination Test) was also definitely impaired, whereas finger tapping speed and static steadiness generally were borderline or only mildly impaired (i.e.,

less than 2 SDs below normal expectation). Grip strength decreased slightly among MS patients but remained average. Among tests of "higher order" abilities, only the Trail Making Test, which is motorically dependent, showed significantly worsened scores for MS patients. The TPT was poorly executed by both the MS and control subjects; however, control subjects showed improvement, whereas the performances of the MS patients were essentially unchanged. The worsening on motor proficiency measures for patients with MS was consistent with previous research (Goldstein & Shelly, 1974; Matthews et al., 1970; Reitan et al., 1971).

An unexpected finding was that the motor deterioration for MS patients appeared to be more evident on dominant than nondominant hand measures. This suggestion evolves from the post facto *t* test analyses in which dominant hand test-retest comparisons on the pegboard, finger tapping, and static steadiness measures either approached or achieved significance, but nondominant hand performances on these same tests did not. On several of these motor tests (e.g., finger tapping and steadiness measures), the control subjects showed bilateral improvement. The clinical or neuropathological (or both) significance of this observation is uncertain, but it raises the possibility that deterioration associated with MS is more apparent, and subsequent referral for neuropsychological reevaluation is therefore pursued, as the efficiency of dominant hand performance is affected—suggesting a possible sampling bias among the MS patients.

Several of the tests of sensory discrimination abilities also appear to be sensitive to MS. The number of errors on the Fingertip Number Writing Test increased dramatically in the follow-up MS data, as did the time scores on the Sandpaper Roughness Discrimination Test. The stereognostic abilities of the MS patients were significantly worse than those of control subjects, both in initial and in follow-up testing, but no statistically significant deterioration was identified. In considering these data, it must be appreciated that an unknown degree of the motor-sensory deterioration seen in MS may reflect plaque

formation below the level of the cerebral hemispheres.

In addition to the worsened performances over time on motor-dependent measures and several sensory-perceptual tests, the MS group consistently showed either unchanged or worsened scores on all other tests of adaptive abilities. This observation was in sharp contrast to the opposite tendency for non-MS neurological control subjects to improve on many of these same tasks. Improvement by the control group may indicate improvement of adaptive skills, a "practice effect," or both. The fact that the mean test-retest interval was almost 3 years suggests that any practice effect would most likely be minimal. The probability that the test-retest differences represent a true improvement in neuropsychological function for the control group is supported by the fact that several of the neurological disorders of the control group involved neurosurgical procedures from which recovery of function over time could reasonably be anticipated.

Neuropsychological decrements over time were also evident on several tests of higher order cognitive skills. Verbal, Performance, and Full Scale IQs on the WAIS achieved statistical significance, as did the Wisconsin Impairment Index. The WAIS measures were primarily influenced by worsening of MS, whereas the Impairment Index reflected not only the exacerbation of adaptive ability deficits in the MS group but also improved performances by the non-MS neurological controls. The worsened Impairment Index ratings for MS patients seem to be largely attributable to the changes evident on the Trail Making Test and the TPT, each of which is heavily motorically dependent. The Seashore Rhythm and the Speech Perception tests yielded no significant findings, but the Category Test results demonstrated a mild improvement over time that was most prominent for the control subjects.

It is somewhat surprising that WAIS variables should prove to be sensitive to the effects of demyelination when many other measures that are commonly considered to be more sensitive indices of brain dysfunction (Reitan, 1959a) yielded negative or equivocal

results. These unanticipated psychometric findings are further highlighted by the observation that the Information, Vocabulary, and Digit Symbol WAIS subtests were the measures that proved to be most sensitive to MS deterioration. The worsening of Digit Symbol scores in the MS sample may be related to this test's dependency on a visual-motor response, but worse scores on the Information and Vocabulary subtests cannot be explained on a visual-motor basis. Furthermore, these two subtests are commonly considered to be relatively insensitive to neurological disorders (in the absence of aphasia). Several WAIS subtests that are more often sensitive to neurological dysfunction failed to yield significant decrements for the MS group. The Digit Symbol, Picture Arrangement, and Block Design subtests either approached or achieved statistical significance on the analyses of tests across groups, with slightly worsened functioning evident on these measures regardless of neurological diagnosis. Even though it is of interest to note that many of the individual WAIS subtests, in addition to the summary IQ scores, achieved statistical significance, the clinical import of these findings may be minimal, because the absolute mean values on these measures were not strikingly changed in either diagnostic group. Although other tests of complex cognitive functions yielded statistically significant results, the actual level of impairment was not strikingly changed when the various neurological patient performances were compared against expectations based on normative data (Figure 1).

One ability domain that Beatty and Gange (1977) suggested as being particularly sensitive to demyelination is memory. Several different tests requiring attention-memory skills in this study found no support for significant memory impairment, but it must be remembered that the tests used here were brief clinical assessment procedures and were not the more rigorous techniques used in the experimental learning-memory literature.

The MMPI data are interesting for their implications for future research, but the current sample size was too small to permit any conclusions. Group profiles suggest an in-

creased concern with physical integrity that may be more frequent in MS. This concern probably reflects the actual disease process of MS. Neurological dysfunction in general appears to be associated with worsening depression, increased sensitivity to perceived or real criticism, and increased denial. Finally, there is the suggestion that MS patients may be less anxious than non-MS neurological controls. Future research into the MMPI correlates of MS will hopefully correlate group or individual (or both) MMPI profiles with clinical-behavioral status at the time of testing.

This study offers some encouragement to the MS patient and to professionals active in the patient's therapeutic and social-vocational planning. The generality of any conclusion drawn from this research is limited to those MS patients who remain capable of taking neuropsychological examinations. Nevertheless, the knowledge that one can reasonably expect to retain much of the premorbid intellect over an extended time interval may serve to keep the realistic anticipation of worsened motor skills and sensory-perceptual abilities in a broader and less catastrophic personal-social-vocational perspective.

The Generalized Expectancy for Success Scale— A New Measure

Bobbi Fibel and W. Daniel Hale
University of Massachusetts

A new measure of generalized expectancy for success was assessed for its psychometric properties. Three samples of Caucasian, middle-class college students participated in the study. The first sample ($n = 100$; 59 females, 41 males) received a preliminary version of the Generalized Expectancy for Success Scale (GESS). Item analysis yielded 30 items that were substantially correlated with the total score but were not significantly related to social desirability. The second sample ($n = 104$; 63 females, 41 males) received the 30-item GESS twice at a 6-week interval. The third sample ($n = 103$; 69 females, 34 males) received the GESS, the Marlowe-Crowne Social Desirability Scale, the Internal-External Locus of Control Scale, the Self-Rating Depression Scale, the Depression Inventory, and the Hopelessness Scale. Results indicate that the GESS has acceptable test-retest reliability, high internal consistency, and minimal relationship with social desirability. Predicted relationships between high generalized expectancy for success, depressive symptomatology, and internality were supported. Factor analysis indicated that GESS scores are a function of one general factor. Further construct validation is reviewed, and implications for future use of the GESS are discussed.

One of the key concepts of Rotter's learning theory (Rotter, 1954; Rotter, Chance, & Phares, 1972) that has been the subject of considerable study in recent years is that of generalized expectancies. The two generalized expectancies that have received the most attention, and for which there are reliable and valid measures, are expectancies regarding internal-external control of reinforcements (Lefcourt, 1976; Phares, 1976; Rotter, 1966, 1975; Strickland, 1977) and interpersonal trust (Rotter, 1967). The purpose of the present ongoing investigation is to construct and validate a measure of a different generalized expectancy—the generalized expectancy for success. This construct can be de-

fined as the expectancy held by an individual that in most situations he/she will be able to attain desired goals. According to social-learning theory, an individual's behavior potential is a function of reinforcement value and expectancies that are determined by a person's reinforcement history for relevant situations. Therefore, when other factors are held constant, the behavior potential for an individual with a high expectancy for success should be greater than that of an individual with a low expectancy for success. Further, since situations vary in the extent to which a person's reinforcement history is relevant, expectancies for success may vary along a continuum from relatively specific to general, as a function of the degree of situational novelty or ambiguity. Numerous studies (Dickstein & Kephart, 1972; Feather, 1966; Feather & Saville, 1967; Rosenthal & Jacobson, 1966; Tyler, 1958) have demonstrated that individuals experimentally given a high expectancy for success on a certain task or set of tasks are indeed more likely to perform more successfully than those given a

low expectancy for success. Unlike these experimentally induced task-specific expectancies, however, situations seldom provide individuals with explicit expectancies for success. More commonly, individuals face relatively unfamiliar or ambiguous circumstances for which no highly specific expectancy has been provided or formulated. A person's behavior in such situations is still largely influenced by his/her expectancy for success, but this expectancy increasingly becomes a function of generalized expectancy as the degree of novelty or ambiguity increases. Just as the construction of a measure of internal-external locus of control allows researchers to move from situationally induced skill versus chance expectancies for control to internal-external control as an individual difference variable, the Generalized Expectancy for Success Scale (GESS) allows researchers to explore individual differences as a function of generalized expectancies for success.

A valid and reliable measure of a generalized expectancy for success can facilitate the study of factors in the development of such expectancies, situational characteristics that influence expectancies, and the impact of a generalized expectancy for success on a variety of goal-oriented behaviors and other theoretically related cognitive constructs. Thus, the GESS can potentially enhance prediction and clarify issues of theoretical importance. The development of such a scale depends not only on firm grounding in psychological theory but also on adherence to sound psychometric principles and extensive construct validation.

Method

Subjects

Three samples were obtained, each from large undergraduate psychology classes at a large, northeastern university. Students, predominantly middle-class Caucasians, were given the option to participate in studies of their own choosing for bonus academic points. A preliminary version of the GESS was administered to the first sample ($n=100$; 59 females, 41 males) during a class period. The second sample ($n=104$; 63 females, 41 males), solicited in the same manner, was group tested in the 4th and 10th weeks of the semester during the first 20 minutes of the class periods. In the third sample ($n=103$; 69 females, 34 males), subjects volunteered for one

of several small group-testing sessions based on the preliminary description given by the experimenters, one male and one female Caucasian graduate student.

Test Construction

Initially, an attempt was made to construct items that both sampled across situational domains (such as public, private, familial, interpersonal, and work related) and did not specify criteria for success. One hundred fifty items were constructed by the experimenters. The 150 items were then screened for face validity by three psychologists. One hundred four items were selected and subsequently administered to the first sample of 100 subjects. An item analysis yielded 30 items that were substantially correlated with total score ($r > .50$) but were not significantly related to social desirability ($p > .10$) as measured by the Marlowe-Crowne Social Desirability Scale (Crowne & Marlowe, 1960). These 30 items constitute the current version of the measure (see Appendix). All items begin with the same stem phrase: "In the future I expect that I will . . ." which is printed at the top of each page. Responses to items are in Likert format. Subjects are instructed to circle a number on a 5-point scale from 1 (highly improbable) to 5 (highly probable) for each item. Seventeen items are phrased in the positive or success direction and 13 in the negative or failure direction. Items are randomly ordered. The scale is scored additively and in the direction of success, such that a high total scale score indicates a high expectancy for success.

Procedure

The second sample of subjects ($n=104$) was run during fall 1975 and received only the GESS on two occasions for test-retest reliability purposes. The third sample of subjects, run in groups of 10-15 during spring 1975, received the GESS, the Marlowe-Crowne Social Desirability Scale, Rotter's Internal-External Locus of Control (I-E) Scale (Rotter, 1966), the Self-Rating Depression Scale (Zung, 1965), Beck's Depression Inventory (Beck, 1967), the Hopelessness Scale (Beck, Weissman, Lester, & Trexler, 1974), and a questionnaire assessing suicidal ideation (Crepeau, Note 1). Responses to the 30 GESS items were intercorrelated, and the resulting matrix was factored by the principal components method. Components were rotated to orthogonal simple structure by means of Kaiser's (1958) varimax method. Minimum eigenvalue for factor rotation was 1.50.

Results

The test-retest correlation coefficient of the GESS using scores taken at a 6-week interval from subjects in the second sample

** $p < .01$.

who were present for both administrations ($n = 74$; 46 females, 28 males) was .83 overall (.89 for males and .80 for females). Means and standard deviations on the GESS were not significantly different for this sample from those obtained as a function of group testing with additional measures, nor were differences in responding found as a function of sex. Consequently, data from the second and third samples were combined for analyses of psychometric properties ($n = 207$, 132 females, 75 males). The possible range of total scores is 30–150, with higher scores indicating a high expectancy for success. Actual total scores ranged from 65 to 143 for females and from 81 to 138 for males. The mean score for females was 112.32 (mode = 112, $Mdn = 113.14$) and for males, 112.15 (mode = 109, $Mdn = 112.88$). The respective standard deviations were 13.80 and 13.24.

Two measures of internal consistency were computed. The split-half reliability coefficient for odd versus even items, using the Spearman-Brown correction formula, was .90 for females and .91 for males. The correlation between the first 15 items and the last 15 items, again using the Spearman-Brown correction formula, was .82 for females and .83 for males. In view of the fact that all items have a single stem, the high internal consistency is not surprising. However, it should be noted that these reliability coefficients also occur across items that reflect a number of diverse areas.

Correlations with other measures were computed separately for males and females in the third sample. For both sexes it was found that scores on the GESS were correlated negatively and significantly with scores on the Zung Self-Rating Depression Scale, the Beck Depression Inventory, and the Beck Hopelessness Scale (see Table 1). Individuals with low expectancies for success were more likely to report depressive symptomatology and to report themselves as feeling hopeless about impending life events. Even though items with high social desirability bias were eliminated from the original item pool, a low but significant correlation between scores on the GESS and scores on the Marlowe-Crowne Social Desirability Scale was found for females ($r = .25$, $p < .02$) but not for males ($r = .15$, $p > .10$) in the third sample. Also, high GESS scores were significantly correlated with internality as measured by Rotter's I-E scale for females but not for males.

A factor analysis was also computed using the varimax rotation method, which yielded four factors. Variance accounted for by each factor was 63.9%, 13.4%, 12.7%, 10.1% for Factors 1–4, respectively.

Items loading on Factor 1 reflect an individual's sense of general efficacy (Items 4, 8, 9, 10, 12, 13, 15, 16, 21, and 22). For example, the two items with the highest loading within Factor 1 were Item 4, "be unable to accomplish my goals" (.56), and Item 21, "succeed at most things I try" (.55).

Factor 2 was composed of Items 14, 17, 24, 25, 26, 29, and 30. The content of these items primarily involves long-range career-oriented expectancies. Items with the highest loading within Factor 2 were Item 26, "attain the career goals I have set for myself" (.56), and Item 30, "achieve recognition in my profession" (.53).

Factor 3 contained items related to personal problem solving (3, 5, 6, 11, 19, 20, 23, 28). Item 5, "have a successful marital relationship" (.59), and Item 29, "be very successful working out my personal life" (.51), loaded highest among the items in the third factor.

Factor 4 consisted of Items 1, 2, 7, 18, and 27 with Item 1, "find that people don't seem to understand what I am trying to say" (.55),

and Item 18, "find that no matter how hard I try, things just don't turn out the way I would like" (.54), having the highest loadings on the fourth factor. Although effort rather than outcome seems to characterize several items of Factor 4, this is not a consistent theme. In addition, all of the items in Factor 4 are phrased negatively, which suggests a possible overriding response bias. The final factor, then, is not easily interpretable.

Although the factor analysis did yield a moderately interpretable factor structure, other results militate against assuming the simple factor structure noted above. First, Factor 1 accounted for a disproportionately high percentage of the variance. In addition, 15 items, half of the scale items, loaded greater than $\pm .30$ on at least two and in some cases three factors. The considerable overlap in loadings on the four factors suggests that the factors are not independent. The small sample size and lack of uniformly interpretable factors further limit the validity of a

simple structure. Based on current data, the presence of one general factor is tentatively reasonable. Subsequent factor analyses using larger samples and separate analyses for males and females may prove more conclusive.

Discussion

Results indicate that the GESS has an acceptable test-retest reliability, high internal consistency, and a minimal relationship with social desirability. Preliminary factor analysis did not yield strong evidence of a simple subscale structure. It appears that GESS scores are largely a function of one factor reflecting a sense of general efficacy.

A number of theoretical approaches to depression—learned helplessness (Seligman, 1975), social learning theory (Phares, 1972), and Beck's (Beck, 1967, 1976) model among them—focus on the importance of the depressive's negative cognitive set. To estab-

lish the construct validity of the GESS, an assessment of its scores in relation to measures of depressive cognition is crucial. As expected, the GESS was significantly related to measures of depression, with persons who express high expectancies for success being less likely to report themselves as depressed. This relationship has been further corroborated with samples of college students (see Table 2; Koerner, 1977; Crepeau, Note 1; Strickland, Note 2). The significant negative correlations with the Hopelessness Scale obtained in the present investigation provide further support for the construct validity of the GESS, since Beck et al. (1974) have demonstrated that their scale is a quantitative measure of pessimism. Extreme pessimism or helplessness is also correlated with suicide (Minkoff, Bergman, Beck, & Beck, 1973). In Crepeau's (Note 1) study, retrospective self-report data on the frequency of suicidal ideation among college students correlated negatively and significantly with GESS scores. Thus, low scores on the GESS are related consistently to measures of negative cognition, depressive affect and symptomatology, and suicidal ideation.

Anxiety, frequently a concomitant of depression (Beck, 1967, 1976) and an anticipated correlate of low generalized expectancy for success, related negatively and significantly to GESS scores in both Strickland's (Note 2) and Koerner's (1977) studies. An individual with a low generalized expectancy for success tends to report greater anxiety as measured by the Multiple Affect Adjective Checklist (MAACL; Zuckerman, Lubin, & Robins, 1965). Additionally, Koerner reported a significant negative correlation between scores on the Hostility subscale of the MAACL and GESS scores. As in the female sample of the present study, social desirability was positively correlated with GESS scores for the combined male and female samples of Koerner's study ($r = .29$, $p < .01$). However, after partialing out the effects of social desirability, the relationship between GESS and depression scores remained significant ($r = -.44$, $p < .001$).

Numerous studies have demonstrated a positive relationship between an individual's belief in internal control of reinforcement and successful coping behaviors (Lefcourt, 1976; Phares, 1976, Strickland, 1977; Gilmore,

Note 3). In the present study, high GESS scores were related to internality for female subjects but not for males. Other studies by Strickland (Note 2), Crepeau (Note 1), and Koerner (1977) demonstrated the relationship between GESS and internality for both sexes (see Table 3). Crepeau used the Collins (1974) and Levenson and Miller (1976) subscales derived from the factor analyzed I-E scale to measure locus of control. Crepeau found GESS scores negatively and significantly related to each of the five subscales (difficult/easy world, just/unjust world, predictable/unpredictable world, politically responsive world, and personal control) for female subjects and all but the fourth subscale (politically responsive world) for male subjects (trend, $p < .10$). Using an academic achievement measure that distinguishes between positive and negative events of locus of perceived responsibility (Crandall, Note 4), Strickland reported significant negative correlations between GESS scores and total I-E scores and internality for positive but not negative events for female subjects. For males, GESS scores were negatively and significantly correlated with I-E scores on the positive, but not the negative events, subscale. In summary and as expected, GESS scores and a belief in internal control of reinforcement appear to be related both at a general level and across specific dimensions. These relationships seem somewhat attenuated among male subjects. Discriminant validity is demonstrated by the low and generally insignificant correlations between GESS scores and scores on the Social Desirability Scale and the MAACL Hostility subscale.

Support for the construct validity is provided by Fibel (1976). She investigated the relationship between an individual's generalized expectancy for success, task-specific expectancies for success, and differential responses to a learned helplessness paradigm with college females. Data analysis showed a significant positive correlation between GESS scores and specific expectancies for success in novel and ambiguous situations and relatively lower correlations as specific situational information was acquired. Thus, as postulated, one's specific or immediate expectancy increasingly becomes a function of one's

generalized expectancy as the degree of novelty or ambiguity is amplified.

The choice of a measure of generalized versus specific expectancy for success must be determined by the level of analysis desired. Measures of task-specific expectancies will be of greater predictive utility when the level of analysis is task focused. For example, then, the intent of predicting successful performances on mechanical tasks is better determined by a measure of expectancy tailored to mechanics than by a generalized measure. Similarly, measures of specific expectancies within a single need area, such as academic achievement, are preferable when one's predictive purposes are tied to that need area. A generalized measure will be most useful when the level of analysis is broadly defined as an assessment across need areas and situations or in novel or ambiguous circumstances.

Several cogent issues remain unresolved. The degree of relationship between GESS and measures of other personality variables such as self-esteem has not been investigated. The validity of this instrument for populations other than college students must be demonstrated. Additional factor analyses are needed to support the unidimensionality of the measure. The influence of social desirability on GESS scores while moderate for a measure of a culturally highly valued construct must be taken into account in future work with the scale. Nonetheless, at this point, the GESS appears to be theoretically well-founded, empirically sound, and shows promise of predictive utility. Additionally, its brevity and ease of administration further enhance its value. Anticipated are relationships between the GESS and achievement, assertiveness, risk taking, persuasibility, interpersonal skills, and social competence. Further, a measure of this possibly potent cognitive-mediating variable may have implications for predicting psychological well-being, particularly vis-à-vis depressive symptomatology that is typically characterized by negative expectations and low motivation.

Appendix

The Hale-Fibel Generalized Expectancy for Success Scale

This is a questionnaire to find out how people believe they will do in certain situations. Each item consists of a 5-point scale and a belief statement regarding one's expectations about events. Please indicate the degree to which you believe the statement would apply to you personally by circling the appropriate number. [1 = highly improbable, 5 = highly probable.] Give the answer that you truly believe *best applies to you* and not what you would like to be true or think others would like to hear. Answer the items *carefully*, but do not spend too much time on any one item. Be sure to find an answer for *every item*, even if the statement describes a situation you presently do not expect to encounter. Answer as if you were going to be in each situation. Also try to respond to each item independently when making a choice; do not be influenced by your previous choices.

In the future I expect that I will

1. find that people don't seem to understand what I am trying to say.
2. be discouraged about my ability to gain the respect of others.
3. be a good parent.
4. be unable to accomplish my goals.
5. have a successful marital relationship.
6. deal poorly with emergency situations.
7. find my efforts to change situations I don't like are ineffective.
8. not be very good at learning new skills.
9. carry through my responsibilities successfully.

10. discover that the good in life outweighs the bad.
11. handle unexpected problems successfully.
12. get the promotions I deserve.
13. succeed in the projects I undertake.
14. not make any significant contributions to society.
15. discover that my life is not getting much better.
16. be listened to when I speak.
17. discover that my plans don't work out too well.
18. find that no matter how hard I try, things just don't turn out the way I would like.
19. handle myself well in whatever situation I'm in.
20. be able to solve my own problems.
21. succeed at most things I try.
22. be successful in my endeavors in the long run.
23. be very successful working out my personal life.
24. experience many failures in my life.
25. make a good impression on people I meet for the first time.
26. attain the career goals I have set for myself.
27. have difficulty dealing with my superiors.
28. have problems working with others.
29. be a good judge of what it takes to get ahead.
30. achieve recognition in my profession.

Assessing the Impact of Life Changes: Development of the Life Experiences Survey

Irwin G. Sarason, James H. Johnson, and Judith M. Siegel
University of Washington

This article describes the development of a new instrument, the Life Experiences Survey, for the measurement of life changes. It was designed to eliminate certain shortcomings of previous life stress measures and allows for separate assessment of positive and negative life experiences as well as individualized ratings of the impact of events. Several studies bearing on the usefulness of the Life Experiences Survey are presented, and the implications of the findings are discussed.

During recent years, numerous studies have investigated the relationship between life stress and susceptibility to physical and psychological problems. Most of these studies have been based on the assumptions that (a) life changes require adaptation on the part of the individual and are stressful, and (b) persons experiencing marked degrees of life change during the recent past are susceptible to physical and psychiatric problems.

There is considerable evidence that a relationship exists between life stress, operationally defined in terms of self-reported life changes, and physical illness (Dohrenwend & Dohrenwend, 1974b). Rahe and Lind (1971) have reported a relationship between life stress and sudden cardiac death. Theorell and Rahe (1971) and Edwards (1971) have provided data suggestive of a link between life stress and myocardial infarction. Holmes (1970) and Rahe (1968) both found a relationship between life stress and major and minor health

changes, and Wyler, Masuda, and Holmes (1971) have shown that life change is related to seriousness of chronic illness.

There also have been studies of non-health-related correlates of life change that have yielded positive results. For example, significant negative relationships between life stress and academic (Harris, 1973) and teacher (Carranza, 1973) performance have been found. Several researchers have demonstrated a relationship between extent of life changes and psychiatric symptomatology (Dekker & Webb, 1974; Paykel et al., 1969). Vinokur and Selzer (1975) and others (e.g., Constantini, Braun, Davis, & Iervolino, 1973) have also found life stress to be related to the occurrence of depression, anxiety, and tension. A comprehensive review of the life stress literature and a consideration of methodological issues in this area of research has been presented by Rabkin and Struening (1976).

Questions of both a methodological and theoretical nature can be raised concerning present methods of assessing life changes. By far the most widely used instrument in life stress research is the Schedule of Recent Experiences (SRE; Holmes & Rahe, 1967). This is a self-administered questionnaire containing a list of 43 events to which subjects respond by checking those events that they have experienced during the recent past (previous 6 months or 1 year). To determine the scoring weights for specific events, Holmes and Rahe (1967) had a large group of subjects rate

This research was funded by the Organizational Effectiveness Research Program, U.S. Office of Naval Research (Code 452), under Contract N00014-75-C-0905, NR 170-804.

The authors wish to thank Kenneth Hoppe, James Larson, and Karen Lindner who have assisted with data collection for these studies. A note of appreciation is also due Ronald E. Smith for his suggestions during various phases of this project.

each of the 43 items with regard to the amount of social readjustment that the various events required. The item *marriage* (assigned a value of 500) was used as an arbitrary standard or anchor point for making ratings. Mean values were obtained for each of the items. These mean values (divided by the constant of 10) were taken to represent the average amount of social readjustment required by the events. The values, termed *life change units*, when summed yield a total life stress score.

Although the development of the SRE represents a valuable initial attempt at the quantification of the impact of life change, its adequacy has been questioned on several counts (Rabkin & Struening, 1976). The SRE was based on the assumption that life changes per se are stressful regardless of the desirability of the events experienced. Therefore, both desirable and undesirable events are combined in determining the life stress score. On the other hand, several writers have questioned the logic of combining positive and negative events (Brown, 1974; Mechanic, 1975; Sarason, De Monchaux & Hunt, 1975). It has been argued that undesirable events (e.g., death of a close family member) may have a very different, and possibly a more detrimental, effect on individuals than positive events (e.g., outstanding personal achievement). It seems reasonable, therefore, to consider conceptualizing life stress primarily in terms of events that exert negative impacts.

Vinokur and Selzer (1975) have provided information that bears on this issue. These investigators used a specially modified version of the SRE, which yielded separate values for positive and negative life change. Several stress-related measures such as self-ratings of depression, anxiety, and tension were used, as well as measures of aggression, paranoia, and suicidal proclivity. The study provided support for a relationship between life changes and several of these measures but only when using a measure of undesirable events. Positive change was not found to be systematically related to the personality measures. Vinokur and Selzer (1975) concluded that

it seems reasonable to reject the notion that adjustment to change per se is the crucial determinant of life stress and its sequelae. Instead, it appears that

the contribution of life events to psychological impairment is mediated by stress that is evoked by some undesirable aspect of the events rather than by change per se (pp. 333-344).

Similar evidence that psychological difficulties are related to undesirable, but not desirable events has been provided by Mueller, Edwards, and Yarvis (1977). It would seem necessary to take this desirability-undesirability dimension into account in the assessment of life change.

Even though it might be advisable to categorize events as being desirable or undesirable for purposes of assessment, there are some difficulties with this approach. For example, events may vary in terms of their desirability depending on the circumstances and perceptions of the respondent. To illustrate, "pregnancy" may be a highly desirable event for a woman who wants a child, but it may be viewed as quite undesirable by an unwed teenager. Given the fact that individuals perceive events differently, it is somehow important to individualize ratings of the desirability of the events that they experience.

A related issue concerns the quantification of life changes. Because individuals vary in how they are affected by events, the values derived from group ratings (such as those used with the SRE) may not accurately reflect the impact that events have on particular individuals. Problems inherent in applying group-derived values to individual cases become obvious when it is noted that certain classes of events listed in the SRE can be quite ambiguous. For instance, if a subject responds to the item *major change in financial status*, it is uncertain if the response refers to a major change in a positive or negative direction. It is not clear that the life change unit associated with major change in financial status is as appropriate to the person who has recently become bankrupt as to the person who has recently inherited a large sum of money. Thus, even though life change units do seem to provide a quantitative measure of overall life change, in some cases, they may not reflect the actual amount of stress resulting from the experiencing of specific events. Findings bearing on this issue have recently been reported by Yamamoto and Kinney (1976). These investigators found life

stress scores, based on self-ratings of the stressfulness of events, to be better predictors than scores derived by using mean adjustment ratings similar to those used with the SRE.

Bearing in mind the methodological issues mentioned above, it would appear that a measure of life stress should possess three characteristics. First, it should include a list of events experienced with at least some degree of frequency in the population being investigated. Second, it should allow for ratings, by respondents themselves, of the desirability or undesirability of the events. Third, it should allow for individualized ratings of the personal impact of the events experienced. The present article describes a new measure of life stress, the Life Experiences Survey (LES), constructed according to these guidelines and describes the results of several studies bearing on its usefulness.

Development of the LES

The LES is a 57-item self-report measure that allows respondents to indicate events that they have experienced during the past year. The scale has two portions: Section 1, designed for all respondents, contains a list of 47 specific events plus three blank spaces in which subjects can indicate other events that they may have experienced. The events listed in Section 1 refer to life changes that are common to individuals in a wide variety of situations. The 10 events listed in Section 2 are designed primarily for use with students, but they can be adapted for other populations. Section 2 deals specifically with changes experienced in the academic environment. Section 1 is appropriate for use with subjects drawn from the general population, whereas both sections are relevant to a student population. (In the present research, responses to items of Sections 1 and 2 were combined in deriving life change scores as this research was conducted with college students.)

The LES items were chosen to represent life changes frequently experienced by individuals in the general population. Many of the items are based on existing life stress measures, particularly the SRE. Others were included because they were judged to be events

that occur frequently and that potentially might exert a significant impact on the lives of persons experiencing them. Thirty-four of the events listed in the LES are similar in content to those found in the SRE (Holmes & Rahe, 1967). In the construction of the present scale, however, certain items were made more specific. For example, the SRE contains the item *pregnancy*, which may be endorsed by women but perhaps not by a man whose wife or girlfriend has become pregnant. The present scale allows both men and women to endorse the item of pregnancy in the following manner: *Female: Pregnancy; Male: Wife's/girlfriend's pregnancy*. The SRE includes the item *Wife begins or stops work*, an item that fails to assess the impact on women whose husbands begin or cease working. The present scale lists two items: *Married male: Change in wife's work outside the home (beginning work, ceasing work, changing to a new job, etc.)*, and *Married female: Change in husband's work (loss of job, beginning a new job, etc.)* Examples of events not listed in the SRE but included here are male and female items dealing with abortion and more general items such as serious injury or illness of close friend, engagement, breaking up with boyfriend/girlfriend, and so forth. Nine of the 10 school-related items are unique to the LES. Finally, some of the events from the SRE thought to be of relatively little consequence (e.g., Christmas, vacation, etc.) were not included, and certain other events were reworded to simplify responding.

The format of the LES calls for subjects to rate separately the desirability and impact of events that they have experienced. Thus, they are asked to indicate those events experienced during the past year (0-6 months or 7 months-1 year)¹ as well as (a) whether they viewed the event as being positive or negative and (b) the perceived impact of the particular event on their life *at the time of occurrence*. Ratings are on a 7-point scale ranging from extremely negative (-3) to ex-

¹ Although the LES provides for the assessment of life change occurring during two 6-month intervals, all analyses to date have involved change scores based on the entire preceding 12-month time period.

tremely positive (+3). Summing the impact ratings of those events designated as positive by the subject provides a *positive change score*. A *negative change score* is derived by summing the impact ratings of those events experienced as negative by the subject. By adding these two values, a *total change score* can be obtained, representing the total amount of rated change (desirable and undesirable) experienced by the subject during the past year. Although the findings cited earlier (Mueller et al., 1977; Vinokur & Selzer, 1975) suggest that this total change score might be less predictive of health-related variables than an index of negative change, this measure was used in the present research to provide further information concerning the relationships between negative change, change per se, and stress-related dependent variables. (The LES is presented in the Appendix.)

For any new instrument it is necessary to obtain certain kinds of information. Normative data should be provided that include information about the effects of demographic variables (e.g., sex). Evidence should also be presented concerning the instrument's stability over time and correlations with relevant dependent measures. Finally, in the case of self-report scales, it should be demonstrated that measures derived from the instrument do not simply reflect the effects of response sets such as the tendency to "fake good." The instrument's scores should not be highly correlated with factors such as social desirability.

Normative Data and an Examination of Sex Differences

The first study undertaken with the LES obtained general information concerning the responses of college students to the instrument and investigated the possibility of differences in response due to sex.

The LES was administered in class to 345 students enrolled in introductory psychology courses at the University of Washington during the fall quarter of 1975. Values were obtained for positive, negative, and total life change scores. Means and standard deviations were derived separately for males ($n = 174$) and females ($n = 171$) on each of these mea-

Table 1
Means and Standard Deviations of Male and Female Respondents on the Life Experiences Survey (LES)

LES score	Males ^a		Females ^b	
	<i>M</i>	<i>SD</i>	<i>M</i>	<i>SD</i>
Positive	9.74 6.87	8.07 5.97	9.57 6.71	6.66 5.51
Negative	6.22 4.66	6.28 4.36	7.04 5.64	7.90 6.43
Total	15.97 11.53	11.08 8.01	16.61 12.35	10.23 8.82

Note. In each case figures in top rows are derived from responses to Parts 1 and 2 combined. Figures in the bottom rows are derived from Part 1 only.

^a $n = 174$.

^b $n = 171$.

asures, and tests for sex differences were conducted.² Data from Section 1 and Sections 1 and 2 combined are presented separately in Table 1. The table shows that there were no significant differences between males and females on any of the three life change measures. It can also be seen that the life change scores of this sample of college students are generally low. Higher values might well have been obtained if subjects from the general population had been surveyed. Finally, it can be noted that the results of this and a number of other studies with the LES have shown that the positive and negative life change scores are essentially uncorrelated.

Reliability of the LES

Two test-retest reliability studies of the LES have been conducted. Both involved subjects drawn from undergraduate psychology courses with a 5- to 6-week time interval between test and retest. There were 34 subjects in the first study and 58 in the second. Responses were scored for positive, negative,

² Data concerning the mean ratings of these events; the frequency of endorsement of various events; and percentile ranks for positive, negative, and total change scores can be obtained without charge from the authors.

and total life changes in each case. Pearson product-moment correlations were computed to determine the relationships between scores obtained at the two testings. Test-retest correlations for the positive change score were .19 and .53 ($p < .001$). The reliability coefficients for the negative change score were .56 ($p < .001$) and .88 ($p < .001$). The coefficients for the total change score were .63 ($p < .001$) and .64 ($p < .001$).

Although the findings of the two studies reported here vary to some extent, perhaps due to the relatively small sample sizes, they suggest that LES is a moderately reliable instrument especially when the negative and total change scores are considered.³ It should be noted that test-retest reliability coefficients found with instruments of this type are likely to underestimate the reliability of the measure. That is, with a time interval of 5-6 weeks, subjects may actually experience a variety of events, both positive and negative, that may be reflected in responses given at the time of retesting. As these changes reflect the actual occurrence of life changes, rather than simply inconsistencies in reporting, it would be inappropriate to consider the total variability in responding as error. As subjects generally seem to report somewhat higher levels of positive than negative change on the LES, it seems possible that the lower reliability estimates found with the positive change measure may be due, in part, to the greater likelihood of positive changes occurring within the time interval between test and retest.

Correlates of the LES

To the extent that the LES measures life stress, its scores should correlate with relevant personality indices. Further, an analysis of the correlational patterns should provide information concerning whether life stress is more usefully conceptualized in terms of negative life change or total life change.

Anxiety, Academic Achievement, Social Desirability, and the LES

A group of 100 male and female students drawn from introduction to personality

courses were administered the LES, the State-Trait Anxiety Inventory (Spielberger, Gorsuch, & Lushene, 1970), and a short form of the Marlowe-Crowne Social Desirability Scale (Strahan & Gerbasi, 1972). Academic transcripts were available for 75 of these students. The correlations among life change scores, anxiety, and grade point average (GPA) are presented in Table 2.

Inspection of these correlations shows that the total and negative change scores correlate significantly and in a positive direction with state and trait anxiety, whereas the positive change score is not significantly related to either measure. Tests for significance of the difference between correlations suggested that positive and negative change scores differ significantly in their correlations with state anxiety ($p < .01$). Although negative change scores were significantly correlated with trait anxiety and positive change scores were not, the difference between these correlations was not significant. Significant correlations between negative change and anxiety have also been found in data collected as part of two other investigations. For a sample of naval personnel ($N = 76$), correlations of .46 ($p < .001$) and .40 ($p < .001$) were found with state and trait anxiety, respectively. With college students ($N = 82$), a correlation of .24 ($p < .05$) has also been found between negative change and anxiety as measured by the Multiple Affect Adjective Checklist (Zuckerman & Lubin, 1965).

With regard to GPA, positive, negative, and total change scores were all found to be negatively correlated with GPA. Even though the correlation between positive change and GPA was smaller than the correlations between the negative and total change scores and this measure, the differences between these correlations were not significant. These results are

³ It should be noted that in addition to the two reliability studies reported here, reliability data are available on one additional small sample of 12 subjects who took the LES on two different occasions as part of another investigation. The time interval between test and retest was 8 weeks. Here, reliability coefficients of .61 ($p < .05$), .72 ($p < .01$), and .82 ($p < .001$) were obtained for positive, negative, and total change scores, respectively.

Table 2
Correlations Between Life Change Scores, Anxiety, and Academic Achievement

LES Life change scores	Anxiety		Grade point average ^b
	Trait ^a	State ^a	
Positive	.04	.03	-.21
Negative	.29**	.46***	-.38***
Total	.24*	.37***	-.40***
Balance (negative - positive events)	-.21*	-.36***	.18

*** $p < .001$.

consistent with other studies that have found significant relationships between life stress (assessed by other measures) and measures of anxiety (Constantini et al., 1973) and academic achievement (Carranza, 1973).

As it seemed reasonable that the effects of positive change might, in part, ameliorate the stress produced by negative experiences, a balance or subtractive score (negative - positive) was also computed for each subject and was correlated with the dependent measures. As can be seen in Table 2, in no case was the balance score more predictive than the positive change score alone, although differences between correlations were not significant. These results are similar to those reported by Mueller et al. (1977) and Vinokur and Selzer (1975), who have found such a balance score to be less predictive of stress-related variables than measures of negative life change.

The relationships between life change scores and the social desirability measure were non-significant. Correlations between positive, negative, and total change scores and social desirability were $-.05$, $.05$, and $.01$, respectively. This suggests that responses to the LES are relatively free from the influence of social desirability response bias.

Personal Maladjustment and the LES

To determine the relationship between life stress and personal maladjustment, the LES and the Psychological Screening Inventory

(PSI) were administered to 75 male and female volunteers drawn from introduction to personality courses at the University of Washington.

The PSI (Lanyon, 1970, 1973) is a 130-item true-false inventory that yields scores on five subscales: Alienation (Al), Social Nonconformity (Sn), Discomfort (Di), Expression (Ex), and Defensiveness (De). The Al scale was designed for "assessing similarity to psychiatric patients," and the Sn scale, for "assessing similarity to incarcerated prisoners." The Di scale appears to be a measure of neuroticism, the Ex scale is a measure of the introversion-extraversion dimension, and the De scale is a measure of test-taking attitude.

Correlations between positive, negative, and total life change scores and the five PSI scales are presented in Table 3. The table shows that negative life change is significantly related to scores on the Sn and Di scales. These findings suggest a relationship between negative change, as assessed by the LES, and certain types of personal maladjustment. Although two PSI scales were correlated with negative change only, the PSI Ex scale was found to correlate significantly with the positive change score. Thus, it would appear that extraverted individuals experience greater degrees of positive change than do introverted persons. The results obtained here are similar to those obtained by Constantini et al. (1973) in their investigation correlating life stress scores, derived from the Holmes and Rahe (1967) scale, with PSI scores. The fact that

Table 3
Correlations Between Life Change and PSI Scores

Life change	PSI				
	Al	Sn	Di	Ex	De
Positive	.14	.03	-.07	.28**	.06
Negative	-.10	.20*	.23*	-.02	-.16
Total	.03	.15	-.10	.18	-.06

Note. PSI = Psychological Screening Inventory; Al = Alienation; Sn = Social Nonconformity; Di = Discomfort; Ex = Expression; De = Defensive-ness.

* $p < .05$.

** $p < .02$.

in the present study PSI measures of personal maladjustment as well as certain of the measures considered earlier (e.g., anxiety) correlate with negative but not with positive change provide further support for the notion that life stress may best be conceptualized in terms of negative change.

Depression, Locus of Control, and the LES

Scores on the LES, the Beck Depression Inventory (Beck, 1967), and the Internal-External (I-E) Locus of Control Scale (Rotter, 1966) were obtained for a sample of 64 (34 males 30 females) college students drawn from undergraduate psychology courses. Correlations between life change scores and these two measures are presented in Table 4. The table reveals a significant relationship between negative change and scores on the Beck Depression Inventory, which is consistent with evidence presented by Vinokur and Selzer (1975), who found negative change to be related to self-ratings of depression. An additional finding of interest is that individuals who report having experienced high levels of negative change appear to be more externally oriented, perceiving themselves as being less capable of exerting control over reinforcement contingencies in their environment.

A Study of Counseling Center Clients

In addition to the findings presented above, life change scores have also been obtained

from a group of students receiving treatment at a university counseling center for psychological problems. Based on earlier findings of a relationship between negative life change and measures of personal maladjustment, it was predicted that this group would differ from a randomly selected group of college students in their negative change scores but not in terms of positive change. The counseling center sample consisted of 18 students (16 females and 2 males). For purpose of comparison, LES records of 18 (16 females and 2 males) students were selected at random from protocols obtained from students enrolled in introduction to personality courses at the University of Washington. (Undergraduates at all academic levels are enrolled in these courses.) Mean positive, negative, and total change scores for these two groups are presented in Table 5.

No significant differences were obtained for the positive and total change scores. The counseling center clients did, however, display significantly higher negative change scores than did the comparison group, $t(34) = 2.21$, $p < .05$. In order to rule out the possibility that these findings are unique to the random sample selected for comparison, a second comparison group ($n = 18$) was randomly drawn from the completed LES protocols of introductory psychology students. Again, significance between group means was found for negative, $t(34) = 2.89$, $p < .01$, but not for positive or total life change. These findings provide additional support for a relationship between negative life change as assessed by the LES and problems of a psychological nature.

Table 4
Correlations Between Life Change, Depression, and Locus of Control

Note. $n = 18$ for both groups.

A Comparison of the LES and SRE Approaches as Measures of Life Change

If the LES represents an improvement over the SRE, it should be possible to demonstrate that measures derived from the LES are more highly related to relevant dependent measures than are SRE scores. Further analyses of some of the data already reported, along with analyses of additional data, were undertaken to provide some basis for comparing these two indices of life stress. The comparisons were accomplished by scoring only the 34 items of the LES that are common to the Holmes and Rahe (1967) measure. These items were scored to yield four measures. Three of these measures were LES positive, negative, and total life change scores derived in the manner described earlier. A fourth measure was derived by applying the life change units used with the SRE to each of the 34 items. It was thus possible to derive a measure comparable to the SRE based on responses to these events. Although these measures were based on 34 rather than the entire 43 items of the Holmes and Rahe scale, it was felt that they would provide an adequate basis for comparing the LES and SRE scoring procedures. Based on the findings reported earlier, it was predicted that the LES negative change score would be more predictive of dependent measures than would the Holmes and Rahe measure. No predictions were made regarding the LES positive and total change scores.

In one comparative study, 69 female subjects from undergraduate human sexuality courses were given the LES, the Beck Depression Inventory, and the State-Trait Anx-

iety Inventory. The four life change measures were derived as outlined above. One somewhat surprising finding was that no significant correlations were found between any of the four life change measures and anxiety. Given the rather consistent finding of a relationship between negative change and anxiety reported earlier, these results might best be attributed to the rather select nature of the sample studied. Significant findings were, however, obtained for correlations with the Beck Depression Inventory. Correlations between positive, negative, and total LES scores and depression were .02, .37 ($p < .01$), and .24 ($p < .05$), respectively. The correlation between the life change unit score, similar to that used with the SRE, and depression was .17 (ns). The difference between the correlations obtained with the LES negative change score and the Holmes and Rahe score was significant, $t(66) = 2.31$, $p < .05$.

A second comparative study of the LES and SRE measures concerned the relationship between these measures and the scores on the PSI. As in the original analysis (which included the entire LES), two PSI adjustment measures were found to be significantly correlated with life change when only 34 items were scored, Sn and Di (neuroticism). Correlations between change scores and these measures are presented in Table 6. As can be seen, the LES negative change scores correlated significantly with both measures of adjustment (Sn and Di), whereas no significant relationships were found between these two measures and the life change unit score. Although the differences between these correlations did not reach statistical significance, the pattern of results does seem to support the

Table 6
Correlations Between LES Change Scores, Life Change Unit Scores (34 items), and Psychological Screening Inventory (PSI) Scale Scores

superiority of the LES measure of negative change.

Discussion

The results of the studies reported here suggest that the LES may be a useful research and, perhaps also, clinical tool. They indicate that negative and total change scores, derived from this scale, are reasonably reliable over a 5- to 6-week time interval, although the positive change score appears to be less stable. Support for the usefulness of the scale is provided by the findings showing that the negative life change score is significantly related to a number of stress-related dependent measures. In addition, scale responses appear to be relatively free from social desirability biases, and the measure is capable of differentiating college students who have sought help for adjustment problems from those who have not.

Other results also suggest that the LES possesses certain advantages over the SRE as an instrument for assessing life stress. These advantages relate particularly to the important distinction between desirable and undesirable change made by the LES. The results show that positive and negative life change scores exhibit different patterns of relationships with relevant dependent measures. It can be noted that there was not a single case in which both positive and negative change scores were significantly correlated with the

same dependent measures. This suggests that the separate assessment of positive and negative change by the LES represents a step forward in assessing relationships between life changes and diverse dependent measures. It seems possible that life stress is most accurately conceptualized in terms of negative life changes rather than in terms of positive or total change. Our findings and those reported by others suggest that it is the negative change measure that should be used if one's purpose is to determine degree of "life stress."

Although the results reported here emphasize the role of negative change, it should be pointed out that the failure to find significant correlations between positive change and the dependent measures may be related to the lower reliability of the positive change score rather than to the unstressful nature of positive life change. The findings of Mueller et al. (1977) and Vinokur and Selzer (1975), which are consistent with the present results, however, support conclusions emphasizing the importance of negative life changes.

A major consideration in the assessment of life stress concerns the nature of the relationships obtained between life change scores and stress-related dependent variables. One might question, for example, whether relationships such as those reported in this article and found elsewhere in the literature reflect the effects of life stress on individuals or simply reflect the effects of specific variables on the reporting of life change. Regarding life stress research in general, one might also question whether persons experiencing high levels of life stress are actually more susceptible to the development of physical and/or psychological problems or whether persons who already manifest such difficulties are more prone to experience life change. Thus, the directionality of the relationships obtained in life stress studies is often unclear. This makes it difficult to draw firm cause-effect conclusions. Although authors such as Brown (1972) have made a strong case for the causal role of life stress, and even though most research in the area seems to be based on the assumption that change plays a causal role, definitive answers regarding cause-effect relationships must ultimately come from longitudinal stud-

ies that are more complex than those typically found in the life stress literature.

Although based on available research findings, it is not possible to resolve this directionality issue even though some data are available regarding the degree to which life stress scores may themselves be influenced by the psychological state of the respondent at the time of testing. In a recent study by Siegel, Johnson, and Sarason (Note 1), the effects of an experimentally induced depressive state on responding to the LES was investigated. The subjects, who had previously completed the LES, were randomly assigned to one of three experimental conditions: neutral, elation, and depression. By using an affect induction procedure developed by Velten (1968), it was possible to induce transient states of elation and depression in these subjects. Subjects were then given the LES a second time. Although a manipulation check indicated that the affect induction procedure did result in elation and depression in the two experimental groups, these mood states had no effect on the number of life changes reported or on any of the LES scores. These results suggest that the significant correlations between the LES and depression do not result from the effects of the depressive mood state on responding to the LES. These results might be interpreted as being consistent with the notion that a causal relationship exists between negative events and depression. However, additional data are needed to draw firm conclusions. (Although mood state does not influence responding per se, depressed individuals as a result of their condition may actually experience more negative changes, thus resulting in a correlation between change and depression.) The results do suggest, however, that responses to the LES are not unduly influenced by the mood state of the respondent.

Finally, in considering the assessment of life change and its effect on individuals, it would seem necessary to take into account the role of variables in addition to life stress. For example, it may be noted that even though significant relationships between change scores and dependent measures were found in this research, the magnitude of the correlations was in most instances low, sug-

gesting that life stress accounts for a relatively small proportion of the variance reflected in the measures. This finding of significant but low correlations is consistent with the results of other life stress studies. It thus seems appropriate to question whether these findings reflect the inadequacy of present life stress measures or if it is, in fact, reasonable to expect such measures to correlate highly with stress-related variables. Dohrenwend and Dohrenwend (1974a) have pointed out that it is likely that the effects of life stress differ from person to person depending on their individual characteristics. Some persons may be greatly affected by even moderate levels of life change, whereas others may be affected very little by relatively high levels. If this is the case, it may not be unreasonable to expect correlations of the low magnitude that have typically been obtained. Perhaps we can expect to find stronger relationships only as variables determining the effects of life change are taken into account.

Unfortunately, relatively little research has been directed toward investigating the role of moderator variables, although the research that has been conducted is provocative. Nuckolls, Cassel, and Kaplan (1972) investigated the relationships between life stress and pregnancy and birth complications. No significant relationships were found among these variables when all subjects were considered. However, when mothers were divided into those who displayed high and low levels of "psychosocial assets," significant results were obtained. Subjects showing high levels of both life change and psychosocial assets (support systems in their environment) did not show evidence of increased complications. Those who displayed high levels of life change and low levels of psychosocial assets did have an increased frequency of such complications.

The importance of moderator variables has also been suggested by the results of a study conducted by Johnson and Sarason (in press) in which the relationships among life change and measures of anxiety and depression were examined as a function of locus of control orientation (Rotter, 1966). It was predicted that a relationship between negative change and depression and anxiety would be found

for externally oriented subjects (who presumably see themselves as having little control over environmental events) but not for internally oriented subjects (who tend to perceive themselves as capable of exerting control over environmental events). The results were in line with this prediction, thus suggesting that life stress may affect individuals differently depending on the degree of their perceived control over events. In one other study, Smith, Johnson, and Sarason (1978) found the relationship between life stress and a measure of psychological adjustment to vary as a function of subjects' scores on a measure of sensation seeking (Zuckerman, Kolin, Price, & Zoob, 1964). Thus, the effects of life stress may also be mediated by self-reported "optimal level of stimulation."

It would appear, then, that one's perception of control over environmental events, sensation-seeking status, and degree of psychosocial assets may all mediate the effects of life stress. It seems likely that there are also other individual difference variables that moderate the effects of life changes, and research designed to identify them is needed. The LES, which possesses sufficient reliability and correlates with a variety of relevant dependent measures, could be used in studies aimed at identifying moderator variables and their effects. The format of the LES allows for the individualized rating of the impact of events plus the availability of separate measures of positive and negative change. This makes it especially appropriate for use in future research concerning how people deal with the stresses and strains of modern life.

Appendix

The Life Experiences Survey

Listed below are a number of events which sometimes bring about change in the lives of those who experience them and which necessitate social readjustment. Please check those events which you have experienced in the recent past and indicate the time period during which you have experienced each event. Be sure that all check marks are directly across from the items they correspond to.

Also, for each item checked below, please indicate the extent to which you viewed the event as having either a positive or negative impact on your life at the time the event occurred. That is, indicate the type and extent of impact that the event had. A rating of -3 would indicate an extremely negative impact. A rating of 0 suggests no impact either positive or negative. A rating of +3 would indicate an extremely positive impact.

Section 1

	0 to 6 mo	7 mo to 1 yr	extremely negative	moderately negative	somewhat negative	no impact	slightly positive	moderately positive	extremely positive
1. Marriage			-3	-2	-1	0	+1	+2	+3
2. Detention in jail or comparable institution			-3	-2	-1	0	+1	+2	+3
3. Death of spouse			-3	-2	-1	0	+1	+2	+3
4. Major change in sleeping habits (much more or much less sleep)			-3	-2	-1	0	+1	+2	+3

	0 to 6 mo	7 mo to 1 yr	extremely negative	moderately negative	somewhat negative	no impact	slightly positive	moderately positive	extremely positive
5. Death of close family member:									
a. mother			-3	-2	-1	0	+1	+2	+3
b. father			-3	-2	-1	0	+1	+2	+3
c. brother			-3	-2	-1	0	+1	+2	+3
d. sister			-3	-2	-1	0	+1	+2	+3
e. grandmother			-3	-2	-1	0	+1	+2	+3
f. grandfather			-3	-2	-1	0	+1	+2	+3
g. other (specify)			-3	-2	-1	0	+1	+2	+3
6. Major change in eating habits (much more or much less food intake)			-3	-2	-1	0	+1	+2	+3
7. Foreclosure on mortgage or loan			-3	-2	-1	0	+1	+2	+3
8. Death of close friend			-3	-2	-1	0	+1	+2	+3
9. Outstanding personal achievement			-3	-2	-1	0	+1	+2	+3
10. Minor law violations (traffic tickets, disturbing the peace, etc.)			-3	-2	-1	0	+1	+2	+3
11. <i>Male</i> : Wife/girlfriend's pregnancy			-3	-2	-1	0	+1	+2	+3
12. <i>Female</i> : Pregnancy			-3	-2	-1	0	+1	+2	+3
13. Changed work situation (different work responsibility, major change in working conditions, working hours, etc.)			-3	-2	-1	0	+1	+2	+3
14. New job			-3	-2	-1	0	+1	+2	+3
15. Serious illness or injury of close family member:									
a. father			-3	-2	-1	0	+1	+2	+3
b. mother			-3	-2	-1	0	+1	+2	+3
c. sister			-3	-2	-1	0	+1	+2	+3
d. brother			-3	-2	-1	0	+1	+2	+3
e. grandfather			-3	-2	-1	0	+1	+2	+3
f. grandmother			-3	-2	-1	0	+1	+2	+3
g. spouse			-3	-2	-1	0	+1	+2	+3
h. other (specify)			-3	-2	-1	0	+1	+2	+3
16. Sexual difficulties			-3	-2	-1	0	+1	+2	+3
17. Trouble with employer (in danger of losing job, being suspended, demoted, etc.)			-3	-2	-1	0	+1	+2	+3
18. Trouble with in-laws			-3	-2	-1	0	+1	+2	+3
19. Major change in financial status (a lot better off or a lot worse off)			-3	-2	-1	0	+1	+2	+3
20. Major change in closeness of family members (increased or decreased closeness)			-3	-2	-1	0	+1	+2	+3
21. Gaining a new family member (through birth, adoption, family member moving in, etc.)			-3	-2	-1	0	+1	+2	+3
22. Change of residence			-3	-2	-1	0	+1	+2	+3
23. Marital separation from mate (due to conflict)			-3	-2	-1	0	+1	+2	+3
24. Major change in church activities (increased or decreased attendance)			-3	-2	-1	0	+1	+2	+3

	0 to 6 mo	7 mo to 1 yr	extremely negative	moderately negative	somewhat negative	no impact	slightly positive	moderately positive	extremely positive
25. Marital reconciliation with mate			-3	-2	-1	0	+1	+2	+3
26. Major change in number of arguments with spouse (a lot more or a lot less arguments)			-3	-2	-1	0	+1	+2	+3
27. <i>Married male</i> : Change in wife's work outside the home (beginning work, ceasing work, changing to a new job, etc.)			-3	-2	-1	0	+1	+2	+3
28. <i>Married female</i> : Change in husband's work (loss of job, beginning new job, retirement, etc.)			-3	-2	-1	0	+1	+2	+3
29. Major change in usual type and/or amount of recreation			-3	-2	-1	0	+1	+2	+3
30. Borrowing more than \$10,000 (buying home, business, etc.)			-3	-2	-1	0	+1	+2	+3
31. Borrowing less than \$10,000 (buying car, TV, getting school loan, etc.)			-3	-2	-1	0	+1	+2	+3
32. Being fired from job			-3	-2	-1	0	+1	+2	+3
33. <i>Male</i> : Wife/girlfriend having abortion			-3	-2	-1	0	+1	+2	+3
34. <i>Female</i> : Having abortion			-3	-2	-1	0	+1	+2	+3
35. Major personal illness or injury			-3	-2	-1	0	+1	+2	+3
36. Major change in social activities, e.g., parties, movies, visiting (increased or decreased participation)			-3	-2	-1	0	+1	+2	+3
37. Major change in living conditions of family (building new home, remodeling, deterioration of home, neighborhood, etc.)			-3	-2	-1	0	+1	+2	+3
38. Divorce			-3	-2	-1	0	+1	+2	+3
39. Serious injury or illness of close friend			-3	-2	-1	0	+1	+2	+3
40. Retirement from work			-3	-2	-1	0	+1	+2	+3
41. Son or daughter leaving home (due to marriage, college, etc.)			-3	-2	-1	0	+1	+2	+3
42. Ending of formal schooling			-3	-2	-1	0	+1	+2	+3
43. Separation from spouse (due to work, travel, etc.)			-3	-2	-1	0	+1	+2	+3
44. Engagement			-3	-2	-1	0	+1	+2	+3
45. Breaking up with boyfriend/girlfriend			-3	-2	-1	0	+1	+2	+3
46. Leaving home for the first time			-3	-2	-1	0	+1	+2	+3
47. Reconciliation with boyfriend/girlfriend			-3	-2	-1	0	+1	+2	+3
<i>Other recent experiences which have had an impact on your life. List and rate.</i>

Young Adult Schizophrenics: Prediction of Outcome and Antecedent Childhood Factors

James D. Roff
Eastern Michigan University

Raymond Knight
Brandeis University

A young adult sample of acute schizophrenics was followed through record sources into middle age. Antecedent childhood information was also obtained. Three aspects of schizophrenia (psychotic thinking, affectivity, and social competence) were assessed in terms of long-term stability and prediction of outcome criteria. Measures of psychotic thinking were found to lack both stability and predictive validity. In contrast, a combined measure of affectivity and social competence was stable over time and was significantly related to eventual outcome. Childhood factors were also related to adult outcome variables. Implications for research definitions of schizophrenia are discussed.

Strauss, Carpenter, and Bartko (1974) have emphasized three underlying processes or dimensions in schizophrenia: positive symptoms, negative symptoms, and disordered social relationships. Positive symptoms primarily involve psychotic thinking, more specifically, the presence of delusions and hallucinations. Negative symptoms refer to the absence of an attribute. Flat or blunted affect is the principal example of a negative symptom, that is, the absence of normal or appropriate affect. Disordered social relationships are related to social competence as measured by the Phillips scale (Phillips, 1953) and other comparable scales.

Strauss et al. (1974) have stated that positive symptoms appear to be prognostically neutral within a schizophrenic sample. Also, they consider that negative symptoms may be confounded with chronicity and possess reduced prognostic value in the absence of chronicity. Disordered social relationships have well-established prognostic validity for schizophrenics as reflected by studies that have used process-reactive or good-poor pre-morbid distinctions.

The present study used a sample of young adult schizophrenics, who in terms of length

of hospitalization and duration of psychosis were acute patients. This allowed the assessment of variables selected to measure psychotic thinking, affectivity, and social competence as prognostic indicators prior to the effects of extended hospitalization. Preschizophrenic information was available from child guidance clinic records. Details of the childhood data analysis have been reported by Roff, Knight, and Wertheim (1976). This prior study found four childhood factors that were then related to a global measure of long-term adult outcome. The present study, in contrast, has focused on factors found during the young adult period and investigated their prognostic significance in terms of subsequent clinical status during the middle adult period. In addition to a global measure of outcome, two factor scales provided more differentiated outcome criterion. The childhood factors, as well as the young adult factors, were assessed with a special interest in the possible differential prediction with regard to the two outcome factor scales.

Previous prognostic studies have indicated a number of significant variables (Nameche, Waring, & Ricks, 1964; Robins & Guze, 1970; Stephens, Astrup, & Mangrum, 1967; Vailant, 1964). These studies suggest that measures of social competence, both work and social adjustment, and measures of affectivity would be most appropriate given the data

available. It was also considered desirable to include measures of psychotic thinking, particularly those that reflect severity.

Related to the prognostic question is the problem of defining schizophrenia for research purposes. In this study, a hospital diagnosis of schizophrenia has been used. This is recognized as an overly inclusive definition but has the advantage that few probable schizophrenics would be initially excluded. Outcome ratings were made that amounted to a rediagnosis of each case based on follow-up information. In addition, the New Haven Schizophrenia Index (NHSI), which was developed as a checklist definition of schizophrenia for research use (Astrachan et al., 1972), was included. The NHSI is similar to other checklists for schizophrenia that are heavily weighted with items that reflect aspects of psychotic thinking. It is desirable for definitions of schizophrenia to involve aspects of the syndrome that possess long-term stability. The concept of process schizophrenia carries with it the notion that a stable underlying condition exists. This study focuses on the related problems of prediction of outcome and the search for definitional aspects of schizophrenia that have long-term stability.

Method

Subjects were 45 males who received a hospital diagnosis of schizophrenia while in the military service. A few cases were diagnosed as schizoid personality in service but were subsequently diagnosed as schizophrenic by the Veterans Administration (VA). Postservice follow-up was possible through the use of centralized VA files. Preservice information was independently obtained from child guidance clinic records. Three separate records sources provided data on the same individuals for childhood (M age = 10.9), young adult (M age = 21.7), and middle adult (M = 43.7) periods.

Postservice VA data were used to establish outcome groups to be used as predictive criteria for the service and childhood information. Each case was assigned a position on a 6-point scale, which reflected severity of impairment and certainty of process schizophrenia. Outcome ratings reflected the independent judgments of the two principal investigators. A consensus was reached for those cases with initial disagreement. Outcome 1 involved recovered cases ($n = 2$); Outcome 2 cases had minimal signs of schizophrenia at follow-up but had neurotic or acting-out character deficits ($n = 16$); Outcome 3

cases were paranoid with emotionally unstable personalities ($n = 6$); Outcome 4 cases had severe schizoid personalities but had minimal thought disorder ($n = 10$), and Outcomes 5 and 6 were considered process schizophrenics, with the former improved for substantial periods ($n = 9$) and the latter unimproved or deteriorated ($n = 4$). Independent clinical judgments that were used as the basis for the consensus outcome ratings had an interrater agreement of 76%. (For further information about the derivation of outcome ratings, see Roff et al., 1976.) Outcome ratings were significantly correlated with other indices of outcome—length of hospitalization, employment history, marital status, and level of VA compensation for psychiatric disability.

Service information was abstracted from military service records, with raters blind to both childhood and postservice information. Six variables were selected as the best available composite measures or global judgments of thought disorder, affectivity, and social competence. These variables included conceptual disorganization (Hautaluoma, 1971), a factor scale with item composition similar to a factor of the same name reported by Lorr, Klett, and McNair (1963); the NHSI (Astrachan et al., 1972); global clinical judgments of severity of thought disorder and severity of affect deficit; and ratings of service social adjustment and service work performance. The global clinical judgments were independently made by the two principal investigators on 5-point scales. The average of the two scores was used. Two research assistants independently used the factor scale and NHSI. The assistants also rated social adjustment and work performance on 3-point scales (good, fair, poor). Again, the average of two scores was used. Acceptable levels of interrater agreement were found for all of the measures, with the range of reliability coefficients from .70 to .97 with a median reliability of .82.

These six service variables were intercorrelated and then factor analyzed with significant factors rotated to an orthogonal, varimax solution. Scales were constructed by a summation of standard scores for relevant variables significantly associated with the obtained factors.

The same variables, but from postservice data, were used to construct additional parallel scales. In addition, the outcome rating, derived from postservice information, served as predictive criteria.

The childhood data had been previously analyzed with four factors reported (Roff et al., 1976). Factor scores were computed for factors of unsocialized aggressiveness, low IQ—poor school achievement, neuroticism, and schizoid syndrome.

The resulting set of variables was then analyzed in terms of longitudinal prediction. The set contained four childhood factor scores, two service scales, two postservice scales, and the outcome rating. Additionally, the stability of the two service scales was evaluated by means of their correlation with the two postservice scales.

Results

Service data were factor analyzed to determine a limited number of dimensions that would provide factor scales for use as variables in the prediction of postservice outcome measures. Table 1 shows the result of the factor analysis for the service data. The first factor was labeled *Psychotic Thinking*, with significant loadings for the variables of conceptual disorganization, NHSI, and global clinical judgments of severity of thought disorder. The second factor, labeled *Affect/Social Competence*, had significant loadings for global clinical judgments of affect deficit, service social adjustment, and service work performance. The scale scores, derived from the three variables loading significantly on each factor, retained the independence of the factor solution ($r = .17$). The first two factors accounted for 72% of the variance. The loading of the affect variable and the social competence variables on the same factor was particularly noteworthy along with the relative independence of the two factors when an oblique rotation was selected.

The factor structure for the postservice data was less differentiated. This was reflected by the fact that the two postservice scales, using similar variables, were significantly correlated ($r = .52$). The postservice scales were highly related to the outcome ratings (psychotic thinking and outcome = .77, affect/social competence and outcome = .73). At follow-up, thought disorder, affectivity, and social competence measures were all significantly related to each other. In contrast, dur-

* $p < .01$.

Table 2
Relationship Between Service and Postservice Scales

Service	Postservice		
	1	2	Outcome
1. Psychotic thinking	.24	.11	.12
2. Affect/social competence	.44*	.51*	.65*

* $p < .01$.

ing the young adult period, the thought disorder measures were relatively independent of affectivity and social competence measures, whereas the later two measures were significantly correlated.

Table 2 shows the relationship of two service scales to the two postservice scales and to the outcome ratings. Clearly, it was the service scale measuring affect deficit and social competence that possessed both long-term stability ($r = .51$) and predictive validity ($r = .65$). In contrast, the Psychotic Thinking scale was neither stable nor predictive. Surprisingly, the Affect/Social Competence scale using service information was a better predictor of severity of psychotic thinking than the service Psychotic Thinking scale, which contained the same variables. Table 2 clearly demonstrates the unfavorable prognostic significance of the Affect/Social Competence factor during the service period, and the Psychotic Thinking factor failed to significantly predict any of the postservice measures.

Childhood factor scores were related to the outcome measures, with special interest directed to differential relationships with the two postservice factor scales. Correlations between the childhood factor scores and the postservice variables are presented in Table 3. Schizoid syndrome was significantly related to high scores on the Psychotic Thinking and Affect/Social Competence scales and to poor outcome. Unsocialized aggressiveness was related to more favorable outcome and more favorable scores on the Affect/Social Competence scale but was not significantly related to level of psychotic thinking. Low IQ - poor school achievement was related to unfavorable scores on the Affect/Social Competence scale. The pattern of correlations for the low

Table 3

Relationship Between Childhood Factor Scores and Postservice Scales

Childhood	Postservice		
	Psychotic thinking	Affect/social competence	Outcome
Unsocialized aggressiveness	-.12	-.35*	-.33*
Low IQ - poor school achievement	.06	.38*	.27
Neurotic symptoms	-.03	-.13	.04
Schizoid syndrome	.38*	.33*	.37*

* $p < .05$.

IQ - poor school achievement factor was all the more remarkable given the significant correlation between the two postservice factor scales. Level of neurotic symptoms did not predict any of the postservice variables. In general, the childhood variables predicted postservice better than service variables.

Classifying cases according to their combined score on the childhood schizoid syndrome and the service Affect/Social Competence scale produced the data in Table 4. Comparing the number of cases above and below the mean for each outcome group, Outcomes 1 and 2 combined were significantly different from Outcomes 5 and 6 combined. Outcomes 3 and 4 were more evenly distributed on their scores. Table 4 suggests that the poor outcome cases not only had high scores on the affect/social competence factor in service, but they also tended to have a poor pre-service history as measured by the childhood schizoid syndrome factor. This indicates a long-standing deficit that existed prior to extended hospitalization.

Although the number of cases was small, Outcome 3 cases were compared with Outcome 4 cases, using a point-biserial correlation with outcome dichotomized. Outcome 4 cases were strongly related to low IQ - poor school achievement childhood factor scores ($r_{pbis} = .68$). Outcome 3 cases were related to childhood unsocialized aggressiveness factor scores ($r_{pbis} = .37$). These relationships were consistent with the hostile-paranoid clinical picture for Outcome 3 and the severe schizoid or inadequate personalities characteristic of Outcome 4. Outcome 3 cases were not significantly different from Outcomes 1 and 2.

Outcomes 5 and 6 had higher scores on the childhood schizoid syndrome when compared with Outcome 4 cases but were not significantly different on the other three childhood variables. Outcomes 5 and 6 were consistently more disturbed than Outcome 4 cases both in service and postservice in terms of psychotic thinking and affect/social competence.

Table 5 summarizes the major findings that relate childhood and service factors to outcome. The neurotic and schizoid childhood factors and the Affect/Social Competence and Psychotic Thinking service factors were consistent in their relationships across all three outcome measures. In contrast, the unsocialized aggressiveness and low IQ - poor school achievement childhood factors were not significantly related to Psychotic Thinking scale scores but were significantly related, in opposite directions, to the Affect/Social Competence scale; and the former was significantly related to more favorable global outcome ratings while the latter approached significance in the unfavorable direction.

Table 4

Outcome by Schizoid Syndrome Plus Affect/Social Competence Scale

Outcome	Scale score	
	Above M	Below M
1, 2	2	14
3	2	4
4	4	6
5, 6	12	1

Note. $\chi^2(3) = 18.87, p < .001$.

Table 5
Childhood and Young Adult Factors in Relation to Outcome

Prognostic significance	Childhood factors	Young adult factors
Unfavorable	Schizoid syndrome Low IQ - poor school achievement ^a	Affect/social competence
Neutral Favorable	Neurotic symptoms Unsocialized aggressiveness ^b	Psychotic thinking

^a Unfavorably related to affect/social competence factor at outcome but neutral with respect to psychotic thinking and of borderline significance in relation to global outcome ratings.

^b Neutral with regard to psychotic thinking factor at follow-up.

Discussion

As with most schizophrenic samples, it is important to consider sample limitations. These include, in addition to sample size, a male sample, individuals with childhood problems (disturbed preschizophrenics), and the exclusion of cases rejected for military service. On the other hand, comparisons have been restricted to within-sample differences for a group that has had similar experiences in terms of child clinic contact, military service hospitalization, and the effects of being labeled schizophrenic. Results were consistent with the claim of Strauss et al. (1974) that positive symptoms are prognostically neutral within a schizophrenic sample. Affect deficit, primarily flat affect, measured the principal negative symptom. In this study, flat or blunted affect was not a product of extended hospitalization. Its appearance early in a subject's career was an unfavorable prognostic sign. Disordered social relationships were related to the clinical judgments of affect deficit. It is plausible that affect deficit arises as a result of a history of impaired social relationships. Flat affect may be a function of chronicity measured not in duration from the onset of psychotic thinking or positive symptoms but from the onset of extreme social maladjustment.

The childhood schizoid factor contained a measure of peer adjustment during childhood and a schizoid scale that included symptoms of apathy, flat affect, and seclusiveness. In other words, the schizoid syndrome included the childhood variables most similar to those in the Affect/Social Competence scale for the adult periods. Unsocalized aggressiveness in

childhood was most common in Outcomes 1, 2, and 3. The primary difference between these groups was the significantly higher level of psychotic thinking at follow-up for the Outcome 3 cases. Otherwise, Outcome 3 cases had a developmental background very similar to the more favorable Outcomes (1 and 2). Outcome 4 cases presented a contrast to Outcome 3 at follow-up with lower levels of psychotic thinking but had higher scores on the Affect/Social Competence scale. During childhood, the Outcome 4 cases were less aggressive than Outcome 3 cases and more inadequate as reflected by lower IQ and poorer school achievement. These results suggest that Outcome 3 cases might be considered poor outcome members of a larger group with generally favorable outcome, whereas Outcome 4 cases might have more favorable outcomes from a group with generally poor outcome.

Attempts to define schizophrenia that are heavily weighted with psychotic thinking such as the NHSI appear less promising than alternative measures of affectivity and social competence. Social competence has been adequately assessed by existing scales. A recent scale developed by Chapman, Chapman, and Raulin (1976) to measure anhedonia may provide a more convenient measure of affectivity. This study suggests that the combination of a social competence measure with one of affectivity may assess an important definitional aspect of schizophrenia with both long-term stability and prognostic relevance. It should be noted that measures of psychotic thinking during the postservice period were highly related to measures of affectivity, social competence, and outcome. It was during

the service period that psychotic thinking was a poor substitute for the other measures. Of course, it is the early stage in which problems of definition and prediction are most challenging.

The results of this study do indicate the stability of some behaviors of schizophrenic subjects over extended periods of time. It appears that adequate assessment of these stable aspects of schizophrenia should be incorporated into research definitions of schizophrenia.

Blood Alcohol Level Discrimination by Alcoholics: The Role of Internal and External Cues

David Lansky, Peter E. Nathan, and David M. Lawson
Rutgers—The State University

Two groups of four chronic alcoholic subjects lived in Rutgers' Alcohol Behavior Research Laboratory for separate 2-week periods. During that time, subjects were taught to attend either to internal or to external cues to blood alcohol level (BAL). During a single training session, subjects received feedback on actual BAL following each of their BAL estimates. During pretraining and posttraining sessions, assessments of BAL estimation accuracy were obtained in the absence of feedback. Prior to training, both groups of alcoholics were equally inaccurate in estimating BAL. During training, when accurate BAL feedback was provided, estimation accuracy increased significantly for both groups. Once feedback of actual BAL was removed during the posttraining test session, however, only externally trained subjects maintained the ability to estimate BAL accurately. It was concluded that unlike the nonalcoholic subjects studied by Huber, Karlin, and Nathan, the alcoholic subjects of this research did not learn to discriminate BAL on the basis of internal feelings and sensations nearly as adequately as they did when they referred to external cues. These findings have important implications for the clinical application of BAL discrimination training.

In recent years the widespread conviction that abstinence constitutes the only legitimate treatment goal for alcoholism has come under increasing scrutiny. Acceptance of abstinence-oriented treatment goals for all alcoholics has been challenged by findings that some alcoholics can acquire and maintain patterns of moderate social drinking without accompanying "loss of control" over intake (Armor, Polich, & Stambul, 1976; Davies, 1962; Pattison, 1968; Popham & Schmidt, 1976) and by the apparent success of alcoholism treatment programs with controlled drinking as an explicit treatment goal (Lovibond & Caddy, 1970; Pomerleau, Pertschuk, & Stinnet, 1976; Sobell & Sobell, 1973, 1976).

Several studies on the utility of controlled drinking-oriented treatment for alcoholism incorporate blood alcohol level (BAL) discrimination training as a component. The most frequently used BAL discrimination training method involves the delivery of accurate feedback on BAL under training conditions designed to sensitize the individual to the affective and physiological ("internal") concomitants of different BALs. Caddy and Lovibond (1976), Vogler, Compton, and Weissbach (1975), and Wilson and Rosen (1975) have concluded that this way to train BAL discrimination gives the alcoholic the ability to monitor level of intoxication and then to use this newfound skill to maintain more moderate BALs.

A review of the basic research findings relevant to this treatment approach, however, failed to confirm that alcoholics can in fact acquire and maintain the ability to discriminate BAL on the basis of internal cue training alone. For example, the positive results of studies by Lovibond and Caddy (1970), Vogler et al. (1975), and Paredes, Jones, and Gregory (1974) are all difficult to interpret

This study was supported by National Institute on Alcohol Abuse and Alcoholism Grant AA00259-07 to Peter E. Nathan. We thank John Miller, Department of Statistics, Rutgers—The State University, and the staff of the Alcohol Behavior Research Laboratory for their essential help in this project.

Table 1

Means for Demographic Characteristics and Drinking Histories of Subjects in the Internal and External Training Groups

Variable	Training		<i>t</i>
	Internal	External	
Age (years)	36.25	35.75	.141
No. years of education	11.75	10.75	.880
No. alcohol-related hospitalizations or treatment programs	1.50	1.75	.205
No. years of problem drinking	15.00	9.50	1.166

Note. $n = 4$. All *t* tests are nondirectional tests for independent samples. $df = 6$.

unequivocally, since BAL discrimination accuracy was not assessed in any of the three studies prior to training or after it was terminated. As a result, it is impossible to know whether the alcoholic subjects of these investigations actually did (a) improve their capacities to estimate BAL accurately and (b) maintain this accuracy when external cues to intoxication (e.g., drink strength, veridical BAL feedback, etc.) were removed.

An investigation designed to study the impact of some of these factors on BAL estimation was recently published by Silverstein, Nathan, and Taylor (1974). Alcoholics were asked to provide BAL estimates on the basis of internal feelings and sensations both when accurate feedback on BAL was provided (during internal cue training itself) and when it was not (during pretraining and posttraining sessions). Although discrimination accuracy improved from the initial baseline period to the subsequent period of training, removal of feedback during a final posttraining phase of the study resulted in a return to pretraining levels of estimation accuracy. In essence, then, this initial pre-post comparison of BAL discrimination by alcoholics did not support the view that alcoholics can learn to discriminate BAL on the basis of internal cues alone.

In contrast, the results of BAL discrimination studies of nonalcoholic social drinkers (e.g., Bois & Vogel-Sprott, 1974; Huber, Karlin, & Nathan, 1976) suggest that this subject population can learn to discriminate BAL on the basis of subjective feelings and sensations. In fact, Huber et al. (1976) found that social drinkers can learn to discriminate BAL

equally well when trained to attend either to internal cues (feelings and sensations) or to external ones (BAL-dose relationships).

To date, however, no study of alcoholic subjects has rigorously explored the efficacy of BAL discrimination training focused on external cues nor has external cue training yet been compared directly to internally focused training. Nonetheless, as noted above, clinical studies of BAL discrimination continue to report attempts to train alcoholics to discriminate BAL via internal cues in the absence of empirical evidence that they can in fact do so. This critical research lacuna emphasizes the importance of a direct comparison of these two BAL discrimination training methods with alcoholics.

The present study was designed to effect just such a comparison. To this end, alcoholic subjects were selected for an essential replication of the Huber et al. (1976) study, which compared the efficacy of external cue training and internal cue training with nonalcoholic social drinkers. It was hypothesized that unlike the nonalcoholic subjects studied by Huber and his colleagues, the alcoholic subjects in this study would be less well able to acquire accurate BAL discrimination on the basis of internal than external training procedures.

Method

Subjects

Subjects were recruited via advertisements placed in regional newspapers. They were offered \$60 per

week to live in the Alcohol Behavior Research Laboratory (described in Nathan, Goldman, Lisman, & Taylor, 1972) and participate in the study.

Four men were selected for each of two training groups. All subjects met the following criteria: (a) more than 2 years of heavy problem drinking; (b) evidence of physical dependence on and tolerance to ethanol; (c) good physical health, with no signs of liver or kidney damage; (d) no evidence of psychosis or chronic brain syndrome; (e) not dependent on prescription or street drugs at the time of the research. A complete physical examination, with appropriate laboratory tests, was given to each subject. Demography and drinking history of the two subject samples is summarized in Table 1. Nondirectional *t* tests for independent samples revealed no significant differences between the two groups on any of these variables.

Apparatus

BALs were measured from breath samples by the Gas Chromatograph Intoximeter, Mark IV (Intoximeters Inc., St. Louis, Missouri).

Procedure

Each subject participated in a total of three sessions. From midnight of the day preceding each of the three sessions, subjects were deprived of all food and beverage. The morning of the session, each subject received one cup of decaffeinated coffee; lunch was served at the end of the session.

Session 1 (pretraining). Session 1 was a baseline session, designed to assess subjects' pretraining BAL estimation accuracy. All subjects consumed a total of six drinks containing 80-proof vodka and tomato juice at 35-minute intervals. Each drink contained a mixture of either $\frac{1}{2}$, 1, or $1\frac{1}{2}$ ounces of vodka, plus enough tomato juice to make a total of 6 ounces of liquid. In this and the other two sessions, these three dosage levels were randomly distributed, with the $\frac{1}{2}$ -ounce dose given once, the 1-ounce dose given twice, and the $1\frac{1}{2}$ -ounce dose given three times in each series of drinks. Accordingly, total consumption of liquid was 36 ounces in a 3-hour period, 7 ounces of which were vodka. Following each drink, a subject completed a postdrink questionnaire, designed to assess his ability to discriminate the amount of alcohol contained in the drink.

Four BAL estimates were made during the course of this session. Neither BAL feedback nor training in BAL estimation were provided during the session. Subjects were required to make their estimates on a scale of 0-150, with 0 representing "cold sober" and 150 representing "very high, about as high as you've ever been." Estimates were scheduled 25 minutes after the second and fifth drinks and 1 hour and $1\frac{1}{2}$ hours after the sixth drink.

Subjects in all sessions spent the time between drinks and BAL estimates in individual bedrooms.

Session 2 (training). Sessions 1 and 2 were separated by a day, during which alcohol was not available.

Drink doses were randomized as they had been during Session 1. Ingestion of drinks took place as it did during the first session, except that subjects were now required to gargle with an anesthetic mouthwash prior to each drink; the gargling served briefly to anesthetize the subject's mouth and upper throat, thereby interfering with his ability to use taste cues to discriminate the amount of alcohol in the drink. As in Session 1, a postdrink questionnaire was completed immediately after a subject had finished each drink.

Depending on the group to which he was assigned, a subject received training in BAL estimation that focused either on external or on internal cues.

External training. Each subject in this group received a programmed learning booklet explaining BAL-dose relationships. The booklet was prepared for each subject individually so that the approximate absorption rate of alcohol that he used was based on his weight and resultant BALs as observed in Session 1. All subjects were taught that they metabolize alcohol at the rate of about 10 points per hour on the 0-150 scale and that an ounce of 80-proof vodka produces a rise of 8, 10, or 12 points, depending on weight and metabolism rate. All subjects were allotted sufficient time (2 hours) to complete their booklets. The results of written tests, administered following completion of the booklet, indicated that all subjects had mastered the material. The training sequence for the remainder of this session was as follows: (a) at bar, gargling and drinks, postdrink questionnaire; (b) in room, 20-minute wait; (c) at Intoximeter, told alcohol content of immediately preceding drink, BAL estimate, BAL feedback; (d) drink sequence repeated.

Feedback from the Intoximeter was converted to the subject's scale of 0-150 (0 = 0 mg%; 150 = 300 mg%).

Internal training. Internal training began with each subject listening to a standard relaxation tape designed to increase awareness of important muscle groups and of the sensations that arise from them during states of tension and relaxation. The tape was played once for 15 minutes. Subjects were asked to sit quietly, focus on, then "tune-in" to the bodily sensations that they were experiencing. To help subjects become further aware of internal states, they were also asked to complete modified versions of the Body Sensation Checklist (Bois & Vogel-Sprott, 1974) and the Mood Adjective Check List (McNair & Lorr, 1964) at this time. Prior to each BAL estimate, the subjects in this group again went through all procedures described above except for listening to the relaxation tape. Accordingly, the experimental sequence for this group was as follows: (a) At bar, gargling and drinks, postdrink questionnaire; (b) in room, 5-minute wait, Mood Adjective Check List, tune-in instructions, Body Sensation Check List; (c) at Intoximeter, BAL estimate, BAL feedback, tune-in instructions; and (d) drink sequence repeated. As

with the external training group, BAL feedback was converted to the 0-150 scale.

The drink-estimate sequence was repeated six times during this session, with two additional estimates programmed 1 and 1½ hours following the last drink.

Session 3 (testing). This session followed Session 2 by a day, during which alcohol was unavailable. Procedurally, it was identical to the first session with two exceptions. First, all subjects were required to continue gargling with the anesthetic mouthwash prior to each drink. Second, subjects in both groups were told the actual alcoholic content of their drinks after completing the postdrink questionnaire. This was done to standardize testing conditions and to ensure that Session 3 provided a fair test of the efficacy of both training procedures. Thus, by making dosage information available, externally trained subjects were provided the minimal information necessary to appropriately utilize their training, whereas internally trained subjects were provided more than sufficient information to fully utilize internal training methods. As a result of this testing procedure, outcome was biased in favor of the internal training method. After each BAL estimate, each subject was required to fill out a postdecision questionnaire, indicating how he had arrived at his particular estimate of BAL. Finally, all subjects were told that they would receive a \$3 bonus for each estimate given this session that was within 5 points of their actual BAL.

Data Analysis

BAL estimation accuracy. BAL estimation accuracy was defined as the absolute difference between actual and estimated BAL. In order to have comparable data points across sessions, only those four BAL estimates in Session 2 (2, 5, 7, and 8) that corresponded in time to those in Sessions 1 and 3 were included in the data analysis. Sessional changes in error scores were analyzed by means of a three-factor analysis of variance (Edwards, 1972), with sessions, groups, and trials (i.e., estimates) as main effects. Within-session data were analyzed by means of two-factor analyses of variance, with groups and trials as main effects. Data analyses included computation of partial correlations (Ferguson, 1971) between actual BAL and BAL estimates, with the effect of between-subject variability partialled out. These analyses were performed for all subjects within a group on a session-by-session basis. Third session mean error scores for the two groups were also compared by means of analysis of covariance (Edwards, 1972), with mean Session 1 error scores as the covariate.

Discriminability of drink strength. To determine whether the three alcohol doses were discriminable from each other, the drink estimates of both training groups were combined for analysis purposes, yielding estimates for eight ½-ounce drinks, 16 1-ounce drinks, and 24 1½-ounce drinks in each session. These within-session data were then subjected to one-factor analyses of variance for unequal *ns* (Edwards, 1972),

with the three dosage levels analyzed to determine the single main effect of dose. Relative drink discrimination accuracy by each of the two training groups was analyzed by comparing drink estimation error scores (defined as the absolute value of the difference between a subject's estimate of the alcoholic content of a drink and actual drink dosage) at all three dosage levels. To this end, within-session error scores were subjected to two factor analyses of variance, with groups and trials as main effects.

Results

BAL Estimation Accuracy

Raw BAL estimation error scores could not be subjected directly to analysis of variance, since an F_{\max} test (Winer, 1962) revealed significant heterogeneity of variance across sessions ($F_{\max} = 118.62$, $p < .01$). A logarithmic transformation (\log actual error score + 1.0) was required to reduce the heterogeneity of variance.

Figure 1 graphs the mean transformed error score of each group in each session. As this

Figure 1. Mean transformed blood alcohol level (BAL) estimation error scores of the alcoholics by session and group.

figure shows, both groups markedly improved estimation accuracy with training. Mean transformed error scores, averaged over groups, were 1.5202 for Session 1, .9548 for Session 2, and .9374 for Session 3. An analysis of variance of these data revealed a significant sessions effect, $F(2, 12) = 5.49$, $p < .02$. Duncan's multiple-range test for differences in session means (Edwards, 1972) revealed significant differences between the mean error score in Session 1 and those in Sessions 2 and 3. Mean error scores in Sessions 2 and 3 did not differ from each other. These results confirm that BAL estimation accuracy improved significantly for both groups with training.

Session 1 (pretraining). No significant effects were revealed by the analysis of variance applied to Session 1 data. Mean transformed error score for internally trained subjects was 1.5368; for externally trained subjects, it was 1.5036. The relationship between BAL estimates and actual BAL was also examined by computing partial correlation coefficients (see Table 2). Although the correlation for the external-training group (.47) was greater than that for the internal-training group (.23), neither of these correlations approached significance. If the degree of correlation between actual and estimated BAL is considered a measure of the ability to accurately monitor changes in actual BAL, then this analysis suggests that neither group of alcoholics was able to monitor these changes to a significant degree during this pretraining session.

Session 2 (training). As noted above and shown in Figure 1, the BAL estimation accuracy of both groups improved markedly in Session 2. A within-session analysis of variance revealed no significant effects for this session; the difference between the mean transformed error score for internally trained subjects of 1.0545 and the score of .8550 for externally trained subjects was not significant. In addition to these lowered error scores, both training groups were more successful at monitoring actual BAL, as evidenced by increased correlations between BAL estimates and actual BAL.

Table 2

Partial Correlations Between Actual and Estimated Blood Alcohol Level for Each Group on a Session by Session Basis

Session	Internal	External
1	.23	.47
2	.66**	.52*
3	-.06	.91***

* $p < .07$.

** $p < .02$.

*** $p < .001$.

Session 3 (testing). An analysis of variance applied to Session 3 data revealed a significant group effect, $F(1, 6) = 7.69$, $p < .035$. No other effects reached significance. The mean transformed error score for the internal-training group was 1.1860; it was .6887 for the external-training group. Mean Session 3 error scores were also analyzed with mean Session 1 error scores as the covariate. This analysis also revealed strong group differences, $F(1, 5) = 6.41$, $p < .053$.

Group differences in Session 3 estimation accuracy appear even more striking when one considers correlations between actual and estimated BALs (see Table 2). Although a high correlation between these scores was attained by internally trained subjects during Session 2, a similar analysis of Session 3 data failed to reveal a similarly high significant correlation for these subjects. By contrast, the correlation attained by the externally trained group in Session 3 was substantially higher than that observed during Session 2.

Discriminability of Drink Strength

An analysis of variance applied to within-session drink estimation data revealed significant differences between estimates given at each dosage level during all three sessions, $F(2, 45) = 14.53$ (Session 1); 4.02 (Session 2); 15.41 (Session 3), all $ps < .03$. Duncan's multiple-range test indicates that estimates at the $\frac{1}{2}$ -ounce dose were less than those at the 1-ounce dose, which, in turn, were less than those at the $1\frac{1}{2}$ -ounce dose (all $ps < .05$). These data show, then, that even when subjects gargled with an anesthetic mouthwash

prior to consuming each drink during Sessions 2 and 3, they could discriminate among drinks of varying doses. When drink estimation error scores of the two groups were compared, there were no group differences in drink estimation accuracy during Sessions 1 and 2. During Session 3, however, internally trained subjects tended to be more accurate (they had lower error scores) than externally trained subjects, $F(1, 6) = 5.73, p < .053$.

Self-Report Measures

Following each Session 3 BAL estimate, subjects were required to describe the means by which that estimate had been made. Externally trained subjects reported having used only the training method that they had been taught during Session 2. Internally trained subjects also reported their estimates, depending on their respective training method; two of these subjects noted, in addition, that they had attended to the number of drinks consumed as a cue to their estimates. Subjects were also asked to describe any difficulties that they had experienced with their respective training modes. No externally trained subject reported any difficulty in this respect. By contrast, internally trained subjects reported that the gargling had detracted from the accuracy of their BAL estimates by masking the taste of their drinks.

Discussion

For the chronic alcoholic subjects who took part in this study, there appears to be little doubt that training in BAL discrimination via external cue training was more effective than training in internal cues. Although all eight alcoholic subjects demonstrated comparable pretraining levels of estimation accuracy and comparable levels of accuracy during a subsequent training session, externally trained subjects were significantly more accurate in their estimates after training ended and feedback was withdrawn.

The relative superiority of the external training mode for these subjects is also reflected by the results of correlational analyses. As noted above, we presume that the de-

gree of correlation between actual and estimated BALs is a direct reflection of the accuracy with which subjects monitored changes in BAL. In this regard, although externally trained subjects were more accurate in the ability to monitor changes in BAL before training began, neither group of subjects was able to do so particularly well at this point. In Session 2, however, when feedback on accuracy in the context of training was provided, internally trained subjects markedly improved their monitoring performance; in fact, their accuracy at this point was marginally beyond that attained by externally trained subjects whose Session 2 accuracy was not substantially improved over that of Session 1. However, once training ended and feedback was removed (during Session 3), the externally trained group substantially improved the accuracy of its BAL monitoring (to .91), whereas the correlation between actual and estimated BAL for the internally trained group returned to its Session 1 level of essentially zero.

The pattern of correlations observed for the externally trained group suggests that BAL feedback alone did not enhance monitoring performance; rather, practice with the external training method itself appears to have been largely responsible for the development and maintenance of highly accurate monitoring. Conversely, as soon as internal training was begun, accurate tracking was observed immediately, but it was maintained for only as long as veridical feedback was available to the internally trained subjects. Thus, monitoring of BAL on the basis of external cues appears to have developed more slowly but to have been more enduring, in large part because it is less dependent on feedback than monitoring by subjects instructed to attend to internal cues.

Several methodological problems may affect the generality of these findings. First, internally trained subjects were provided drink dosage information during Session 3 but not during Session 2; this difference in training and testing conditions may have interfered with the internal discrimination techniques that these subjects were taught. This degree of impact seems unlikely, however, since self-

report questionnaire data indicated that internally trained subjects attended primarily to their feelings and sensations in formulating Session 3 BAL estimates and that external cues, when available, facilitated this discrimination process. In addition, since subjects were able to discriminate among drinks of varying doses in all three sessions, it is unlikely that this procedural variant provided information to which internally trained subjects did not already have access.

A second methodological question that can be raised concerns the specificity of the training information provided to the two groups of subjects. In this regard, externally trained subjects were provided objective information concerning relationships between distinct external cues (i.e., alcohol doses) and BALs. By contrast, internally trained subjects were required to learn their discrimination task using cues that were less distinct and objectifiable. Some authors (e.g., Lovibond & Caddy, 1970) have attempted to circumvent this problem by providing internally trained subjects with some objective information about the relationship between internal cues and blood alcohol levels. (e.g., "At a BAL of .05, you will begin to feel a little unsteady.") This procedure was not followed in the present study because it was felt that if internal cues were linked to different BALs for different subjects, as suggested by Huber et al. (1976), the provision of standardized information might have confused individual subjects by providing them with information that might not have been relevant in their particular cases.

The small number of subjects in our sample limits generalizations that can be drawn from our data. However, these data substantially support preliminary findings of the only other study of BAL discrimination by alcoholics that programmed pretraining and post-training tests of discrimination accuracy (Silverstein et al., 1974). It would appear to be a reliable finding, therefore, that alcoholics are relatively unable to discriminate BAL on the basis of internal feelings and sensations. These findings would bear considerable diagnostic significance if it could also be shown that nonalcoholics have less difficulty discrimi-

nating BAL on the basis of internal cues. For example, Huber et al. (1976), Ludwig and Wikler (1974), Pattison (1976), and Silverstein et al. (1974) have all observed that insensitivity to the visceral events that accompany alcohol intake, as reflected by failure to discriminate BAL on the basis of internal cues, may be functionally related to an alcoholic's inability to control his or her drinking. As already noted, Huber et al. (1976) and Bois and Vogel-Sprott (1974) have reported that nonalcoholics can discriminate BAL on the basis of internal cues. A recent study of nonalcoholics by Maisto and Adesso (1977), however, failed to support these earlier findings. In their study, nonalcoholic social drinkers accurately discriminated BAL only when they knew that they were consuming alcohol; when misled into thinking that they were drinking tonic, the discrimination accuracy of these subjects diminished substantially. It is not clear, therefore, whether the discrimination accuracy of Maisto and Adesso's social drinkers—as well as that of subjects studied by Huber et al. (1976) and Bois and Vogel-Sprott (1974)—was due to discriminated sensitivity to different BALs or to other factors such as subjects' knowledge of BAL dose-response curves and/or their acquiescence to demand characteristics of the experimental paradigm. Given these inconsistencies in data bearing on BAL discrimination skills of social drinkers, the diagnostic significance of alcoholics' apparent inability to discriminate BAL remains equivocal, though their behavioral difference from nonalcoholics in our BAL training paradigm remains real.

The findings reported here bear substantial clinical significance. In the first place, despite elaborate "internal" training procedures developed by other investigators to induce discriminated sensitivity to a range of BALs, our data suggest that a simpler, more effective means of accomplishing the same end is to train alcoholics to attend to the external cues that accompany alcohol intake. More generally, alcoholics' apparent insensitivity to the internal cues that accompany alcohol intake suggests that therapy designed to enhance consummatory self-regulation would be more

properly approached via interventions that focus on external rather than internal sources of control. This conclusion, in turn, suggests that behavioral approaches to alcoholism treatment that focus on environmental determinants of drinking behavior might be more effective with problem drinkers than more traditional insight-oriented therapies.

Cuban Value Structure: Treatment Implications

This article discusses the relationship between cultural variables and psychosocial treatment. It is assumed that in order for psychosocial treatment to be acceptable and effective with a client population, it must be sensitive to the cultural characteristics of that population. The paradigm of planning therapy according to the cultural characteristics of a population is illustrated for Cuban immigrant adolescents. To investigate cultural variables, a Value Orientations Scale was developed based on the work of Kluckhohn and Strodtbeck using 325 subjects. Four factorially derived subscales were obtained. When 208 additional Cuban immigrant and Anglo-American adolescents were compared along the Value Orientations Scale, the Cubans tended to prefer lineality, subjugation to nature, present time, and not to endorse idealized humanistic values, whereas the Americans tended to prefer individuality, mastery over nature, future time, and to endorse idealized humanistic values. The implications of these value differences for the delivery of mental health treatment are discussed.

Cross-cultural conditions have seldom been investigated as variables of individual differences related to the appropriateness of different mental health treatment models. Recently, however, cultural variables have been considered as constituting relevant personal and situational characteristics that require specific culturally sensitive treatment approaches (Weidman, 1975).

In general, the issue of matching clients and treatment techniques to enhance the likelihood of obtaining desired outcomes has received extensive discussion and widespread endorsement in psychotherapy. Paul (1969), for example, has argued that psychotherapy outcome research should be directed toward ascertaining which treatment by whom is most effective for a person with specific characteristics and problems in a particular set of cir-

cumstances. This paradigm for treatment outcome research has received strong support from Bergin (1971), and Kiesler (1969, 1971) among others.

During the past 18 years, almost 700,000 Cubans have migrated to the United States. Approximately 500,000 have settled in the Greater Miami area, comprising about 90% of the local Latin population. Establishing mental health and drug abuse treatment services for the Cuban community have presented serious problems for the providers of these services, because the Cubans did not seek treatment from the established Anglo-American-oriented programs (cf. Ladner, Page, & Lee, 1975). These patterns of health care utilization are consistent with those observed in other Latin groups who, in general, underuse Anglo-American-oriented mental health services (Padilla & Ruiz, 1973). Concomitant with the immigrant status of the Cubans, high levels of behavioral disorders were expected to occur as had been found with other immigrant groups (Al-Issa, 1970; Berry & Annis, 1974; Mezey, 1960). It was urgent, therefore, to develop therapeutic models fea-

sible for attracting and maintaining these Cubans in treatment.

The Problem

The present study is based on the assumption that in order to develop therapeutic models that will effectively attract and maintain clients in therapy, their cultural background must be understood. Specifically, it is postulated that cultural variables constitute an important set of client characteristics that need to be taken into consideration for developing valid statements about the relationship between adolescent Cuban clients in treatment and the appropriateness of treatment models (cf. Kiesler, 1971). It is further hypothesized that an understanding of the cultural differences between Cuban immigrant and Anglo-American adolescents provides a conceptual framework for those aspects of a psychosocial therapeutic model that enhances the appropriateness (and thus the effectiveness) of treatment for a Cuban immigrant adolescent population vis-à-vis an Anglo-American population. As part of a programmatic research effort to investigate the cultural characteristics of Cubans as well as developing and investigating the treatment of behavioral disorders in this population, a study of Cuban/Anglo-American adolescent value differences was conducted. The implications of these value differences for the appropriateness of psychosocial treatment models are discussed.

Theory

Clinical experience in the treatment program and a survey of the literature on cross-cultural comparisons of value orientations suggested that the theory of value orientations developed by Kluckhohn and Strodtbeck (1961) would provide a useful framework for contrasting cultural differences between Cuban immigrants and Anglo Americans. They postulated that to compare profiles between two cultures, it is necessary to delineate common human problems and to investigate the corresponding range of variations or ways of responding to these problems to the two dif-

ferent cultures. They describe five human problems common, in general, to all cultures. The solutions provided by each culture to these problems are indicative of world view or basic value orientations within that culture. From Kluckhohn and Strodtbeck (1961), the following definitions of the five basic areas of human problems and the range of possible solutions to these problems were derived:

1. *Human nature* orientation pertains to a society's perception of innate human qualities in terms of good and evil: (a) good—the human being is perceived as being basically good but corruptible; (b) evil—the human being is perceived as being basically evil but perfectible; (c) neutral—the human being is perceived as neither good nor evil and subject to influence.

2. *Person-nature* orientation refers to the perceived relationship of people to natural and environmental phenomena: (a) subjugation to nature—the person is helpless and at the mercy of nature's forces (worldly or other worldly); (b) mastery over nature—the person is seen as capable of controlling nature, mainly through technology; (c) harmony with nature—person and nature are one, working together in harmony.

3. *Activity* orientation refers to the nature of the behaviors through which a person is judged or judges himself or herself: (a) doing—the person is judged by what he or she achieves and emphasizes success-oriented activities usually including externally measurable activities; (b) being—this variation emphasizes activities that are an expression of existing desires (spontaneous expression), and activity is perceived existentially; (c) being in becoming—the emphasis in this variation is on meditation about one's self, which leads to understanding and self-development.

4. *Time* orientation refers to the meaning or emphasis placed on a particular time period: (a) past—the traditions of the past ought to be maintained or recaptured; (b) present—emphasis is on present time and problems; (c) future—emphasis is on a consideration of the future in solving present problems.

5. *Relational* orientation refers to the nature of a person's relation to other people:

(a) lineal—the way people relate to each other is determined by their relative positions within a hierarchy; (b) collateral—people's relations to each other are determined by a horizontal network. In this network all persons are at the same level and relate to each other as "equals" having a place in the network; and (c) individualistic—people relate to others autonomously, not by hierarchical or lateral networks.

Hypotheses

From anthropological and clinical impressions obtained through the treatment program, the following hypotheses were formulated:

1. Human nature orientation does not differ significantly for Cuban immigrants and Anglo Americans.

2. Person-nature orientation differs significantly between Cuban immigrants and Anglo Americans, with the former endorsing subjugation to nature and the latter, mastery over nature.

3. Activity orientation differs significantly between Cuban immigrants and Anglo Americans, with the former endorsing being and the latter endorsing doing as a preferred activity orientation.

4. Time orientation differs significantly between Cuban immigrants and Anglo Americans, with the former endorsing present and the latter endorsing future as a preferred time orientation.

5. Relational orientation differs significantly between Cuban immigrants and Anglo Americans, with the former endorsing lineality and the latter endorsing individualism as a preferred relationship style.

Method

Subjects

There were two samples in this study: Sample 1 was used in the development of the Value Orientations (VO) Scale; Sample 2 served primarily to test the value differences between Cuban immigrant and Anglo American adolescents. The 533 participants in the study were obtained from various educational institutions, such as high schools, junior colleges, universities, and continuing education centers; from social agencies, such as senior citizens activity centers;

and from other frequently used facilities, such as Cuban medical clinics. All facilities were located in the Greater Miami area.

Sample 1 consisted of 325 persons, including 120 (37%) males and 205 (63%) females. In terms of ethnic background, Sample 1 contained 220 (67.7%) Cuban immigrants, 65 (20.0%) Anglo Americans, 12 (3.7%) non-Cuban Latins, and 28 (8.6%) Black Americans. The average age of Sample 1 was 25.1 years, with a standard deviation of 12.1 and a range from 15 to 77 years.

Sample 2 was comprised of 208 persons, 81 (39%) males and 127 (61%) females, of whom 56 (27%) were Cuban immigrants and 152 (73%) were Anglo Americans. Since the majority of the clients in the treatment program referred to as "identified patients" and labeled as *in need of treatment* by their families were adolescents, Sample 2 was chosen to be representative of this sector of the population in treatment with respect to age. The average age of Sample 2 was 16.4 years, with a standard deviation of 1.4 and a range from 14 to 22 years.

Development of the Value Orientations Scale

Item construction. The first step in the development of the VO scale consisted of preparing an initial set of items reflecting the nature of the five human problems defined by Kluckhohn and Strodtbeck (1961) but in a context relevant to the target population. Each of the problem situations was followed by three statements presenting three possible alternative solutions. The final set of 22 problem situations¹ consisted of 9 relational, 4 human nature, 4 person-nature, 3 time, and 2 activity items. Two parallel forms were prepared. The first form was in Spanish. The second form was devised by translating the original set of items into English. The technique of back translation was used to insure the equivalence of the items (Brislin, 1970).

For each problem situation, the person was required to choose the solution considered best and the solution considered worst. The scores for the keyed responses were as follows: A response of *best* for an item was given a score of 3, a response of *worst* for an item was given a score of 1. If an item was not endorsed as either *best* or *worse*, it was assigned a score of 2. A response for each item could thus range from 1 to 3. Each alternative response was scored as a separate variable. Thus, three alternative responses in each of 22 problem situations produced 66 variables with a score of 1, 2, or 3 for each variable.

Scale construction. Rather than assuming that items should be combined as predicted by Kluckhohn and Strodtbeck's (1961) theory of value orientations, the items were submitted to an empirical test. Fol-

¹ Copies of the original Spanish and English versions of the Value Orientations Scale are available from the first author.

1			
2	.086		
3	.131	.160	
4	.047	-.102	-.012

lowing item construction, the scales were administered to Sample 1. The item responses of Sample 1 were factor analyzed, using an alpha solution and an oblique rotation (Harris-Kaiser, Type I).² Four interpretable factors³ emerged from the analyses, accounting for 14.52% of the total variance, with Factors 1, 2, 3, and 4 accounting for 5.31%, 3.50%, 3.21%, and 2.50% of the total variance, respectively. The factors, although obtained by oblique rotations, proved to be nearly independent of each other. Thus, for all practical purposes, the factor structure obtained can be said to be orthogonal. Table 1 presents the intercorrelations among the factors.

The following scale descriptions flow from the item loadings of each factor: Factor 1 is clearly a "relational factor," consistent with Kluckhohn and Strodtbeck's (1961) relational dimension. The items loading greater than .30 on this factor comprise the Relational scale. A high score discloses an individualistic value orientation in which the locus of responsibility for a person's behavior rests with the individual; "relationships are based on individual autonomy; reciprocal roles are based on recognition of the independence of interrelating members" (Papajohn & Spiegel, 1971, p. 260). A low score reflects a belief in lineality in which the locus of accountability is defined by the social structure; "relationships on a vertical dimension are hierarchically ordered; reciprocal roles are based on a dominance-submission mode of interrelationship" (Papajohn & Spiegel, 1971, p. 260).

Factor 2 is mixed, including primarily relational items in addition to person-nature, activity, and human nature items. The items loading above .30 on this factor comprise the Idealized Humanistic scale. A high score is an endorsement of idealized humanistic values, including a belief in collaterality, egalitarian social systems, and a growth-oriented lifestyle in search of harmony, peace, and spiritual development. A low score indicates low endorsement of these idealized humanistic values and greater personal concern.

Factor 3 is also a mixed variable on the perceived relationship between person and nature and their time orientation. The items loading higher than .30 on this factor comprise the Mastery/Future versus Subjugation/Present scale. A high score represents an engaging approach to life, with emphasis on planning for change at points in time extending away from present into future and a belief in the ability to

overcome the natural forces and harness them for human benefit. A low score reveals a fatalistic acceptance of life's circumstances and a belief that little can be done to counteract the forces of nature to which human beings are subjugated. Temporal focus is on the present, whereas the future is seen as being unpredictable.

Factor 4 is definitely related to the perception of human qualities and impulses. This is consistent with Kluckhohn and Strodtbeck's (1961) human nature dimension. Those items loading more than .30 on this factor comprise the Human Nature scale. A high score reflects a perception of human beings as basically selfish, malicious, and evil. A low score indicates a perception of human beings as basically good although corruptible.

Reliability and validity. Internal consistency or alpha coefficients were calculated for Sample 1 for each factor. Factors 1, 2, 3, and 4 yielded alpha coefficients of .89, .84, .76, and .72, respectively. These coefficients are within the acceptable standards for scales that have achieved internal consistency, thus insuring their satisfactory levels of reliability.

Factorial validity was obtained for the VO scale by ascertaining its internal statistical structure through factor analytic techniques. The factorial composition produced four orthogonal VO subscales with high internal consistencies, thus providing high factorial validity.

Results

Value Comparisons

To compare the value orientations of Cuban immigrants and Anglo Americans, the VO scale was administered to the persons in Sample 2. Their item responses were scored as described above in the item construction section. A monotone scaling model for unspecified distribution forms, also known as a linear model, was adopted to develop the VO scale (cf. Nunnally, 1967). In other words, scores were obtained for each of the four factorially derived subscales of the VO scale by algebraically summing the item scores of all of the items that loaded on each factor. Items

² A factor analysis was also conducted for Sample 1 excluding the Black American sample. The factor structure obtained for this analysis was nearly identical to the factor structure obtained for the full sample. Therefore, the factor analysis for the entire sample was used for this study.

³ The items loading greater than .30 on each of the factors, and their factor loadings are available from the first author. These items also comprise the Value Orientation scales.

** $p < .01$.

*** $p < .001$.

loading positively on the factors were added, and items loading negatively were subtracted. Estimates of the internal consistency of the subscales were calculated for Sample 2. The alpha coefficients for Subscales (Factors) 1, 2, 3, and 4 were .76, .58, .51, and .46, respectively.

The Value Orientations Scale

The scores obtained by Cuban immigrants and Anglo Americans on the four factorially derived VO subscales were compared for Samples 1 and 2; t statistics were computed, and the significance of the obtained differences was determined using two-tailed tests of significance. Table 2 presents the means, standard deviations, and t ratios for the differences between the subscale scores. The subscale scores presented in Table 2 were transformed into standard scores, with a mean of 50 and a standard deviation of 10. Since Sample 1 was used to develop the VO scale, the results obtained with Sample 2 were used to test the hypotheses. An examination of Table 2 indicates that in Sample 2, the groups differ significantly for three of the four VO subscales.

As predicted in Hypothesis 1, there were no significant, $t(206) = -1.32$, differences

between Cuban immigrants and Anglo Americans along the Human Nature dimension (Factor 4).

The single largest difference, $t(206) = 2.92$, $p < .01$, was obtained for the Person-Nature and Time subscale (Factor 3). As predicted in Hypotheses 2 and 4, Anglo Americans tended to value *mastery over nature* and preferred to plan for the *future*, whereas Cubans tended to endorse a *subjugation to nature* orientation and a *present-time* orientation.

It was not possible to test Hypothesis 3 directly with respect to the differences in *activity* orientations between Cuban immigrants and Anglo Americans, since none of the factors included a sufficient number of activity items. Moreover, the small number of these items loading on the factors resulted from an artifact in the development of the original VO scale, which included only two human problems purporting to tap activity value orientations.

As expected from Hypothesis 5, Cuban immigrants and Anglo Americans differed significantly, $t(206) = 2.13$, $p < .05$, along the Relational subscale (Factor 1): Anglo Americans tended to value *individuality over lineality* in interpersonal relations, whereas the converse was true for Cubans.

A significant, $t(206) = 2.27$, $p < .05$, and unexpected difference emerged for the Idealized Humanistic Value subscale (Factor 2): Anglo Americans tended to endorse idealized humanistic values, whereas Cubans tended not to endorse these idealized humanistic values.

The scores obtained by Cuban immigrants and Anglo Americans on the four factorially derived VO subscales were also compared for Sample 1. An examination of Table 2 shows that in Sample 1, the groups differed significantly on two of the four VO subscales.

As with Sample 2, Cuban immigrants and Anglo Americans in Sample 1 (a) did not differ significantly, $t(274) = -1.15$, along the Human Nature dimension (Factor 4) as predicted in Hypothesis 1; (b) differed significantly, $t(274) = 2.22$, $p < .05$, in the Person-Nature and Time (Factor 3) subscale scores in the direction predicted by Hypotheses 2 and 4; and (c) differed significantly, $t(274) = 6.55$, $p < .001$, along the Relational subscale in the direction predicted by Hypothesis 5. Contrary to the findings obtained with Sample 2, Cuban immigrants and Anglo Americans in Sample 1 did not differ significantly, $t(274) = 1.60$, along the Idealized Humanistic Value subscale.

Activity Items

To test Hypothesis 3, the response scores obtained by Sample 2 Cuban immigrants and Anglo Americans on each item solution to the two activity problem situations were compared. The sample used in these comparisons included Sample 2 plus 120 additional high school students of Cuban or Anglo-American background. t statistics were computed, and the significance of the obtained differences were determined using a two-tailed test of significance. The results indicate that Cuban immigrants endorsed both items reflecting a "doing" orientation, $t(326) = 5.55$, $p < .0005$, $t(326) = 2.41$, $p < .02$, significantly more frequently than Anglo Americans, whereas Anglo Americans endorsed both items reflecting a "being" orientation significantly more frequently than Cuban immigrants, $t(326) = 3.11$, $p < .002$; $t(326) = 1.98$, $p < .05$. There were no differences between Cuban immi-

grants and Anglo Americans in their endorsement of the two items indicative of a being-in-becoming orientation, $t(326) = .80$; $t(326) = .21$. These findings are contrary to the prediction in Hypothesis 3.

The item solutions to the two activity problem situations provided by Sample 1 Cuban immigrants and Anglo Americans were also compared using t statistics and two-tailed tests of significance. Again as with Sample 2, Sample 1 Cuban immigrants endorsed both items reflecting a doing orientation significantly more frequently than Anglo Americans, $t(274) = 2.02$, $p < .05$; $t(274) = 2.02$, $p < .05$; Anglo Americans tended to endorse both items reflecting a being orientation more frequently than Cuban immigrants, $t(274) = 1.85$, $p < .07$; $t(274) = 1.79$, $p < .08$; and, there were no significant differences between the groups in their endorsement of "being-in-becoming" items, $t(274) = .17$, $t(274) = .01$.

Factor Structure of Sample 2

To ascertain the generalizability of the VO scale to Sample 2, the item responses of Sample 2 were also factor analyzed, using an alpha solution and an oblique rotation (Harris-Kaiser, Type I). Three of the four factorially derived VO subscales obtained from Sample 1 were discernible in the factors that emerged from Sample 2.

Factor 1, comprising the Relational subscale, proved to be the strongest factor in both Samples 1 and 2, accounting in each case for the largest proportion of the total factor variance. Of the 17 items loading on the Relational subscale, 14 items (82%) also loaded on the first factor of Sample 2.

Factor 2, comprising the Idealized Humanistic Value subscale, emerged as the second strongest factor in both Samples 1 and 2. Of the 13 items loading on the Idealized Humanistic Values subscale, 7 items (54%) also loaded on the same factor for Sample 2. An apparent difference between these factors was observed, however. For Sample 1, the factor that emerged was essentially unipolar, measuring low to high idealized humanistic values. The factor that emerged from Sample 2 was clearly bipolar, ranging from idealized

humanistic values on the one hand to a "life is a jungle" value orientation on the other, with an emphasis on the evil qualities of people and the need for self-protection as a survival measure.

Factor 3 of Sample 1, comprising the Mastery over Nature/Future Time versus Subjugation to Nature/Present Time subscale, emerged also as a factor in Sample 2. Six of the nine items (67%) of this subscale loaded on a factor of Sample 2. In this instance, the factor that emerged for Sample 2 was clearly a mastery over nature/future time versus subjugation to nature/present time factor.

It was not possible to identify a factor for Sample 2, which appeared comparable to the Human Nature subscale measured by Factor 4 of Sample 1.

Discussion

The VO scale was developed using Sample 1, and the hypotheses were tested using Sample 2. However, to ascertain the stability of the results across both samples, each sample was factor analyzed separately, and the value comparisons between Cuban immigrants and Anglo Americans were also conducted separately for each sample. The first two factors emerged strongly in the factor structure of both samples; the third factor emerged from Sample 1 and was replicated partially in Sample 2; and the fourth and weakest factor that emerged from Sample 1 was not identifiable in the factor structure of Sample 2. These differences in factor structure are not surprising, since the factors with the highest eigenvalues replicated better across samples, and the factor with the lowest eigenvalue failed to replicate across samples.

With one exception, the differences in value orientations between Cuban immigrants and Anglo Americans held for both samples. The only exception occurred along the idealized humanistic value dimension. Whereas Sample 2 Anglo Americans were significantly higher than Sample 2 Cuban immigrants on this value, the same two groups in Sample 1 did not differ significantly along this dimension. Since Sample 2 subjects were younger (M age = 16.4) than Sample 1 subjects (M age

= 25.1), it is suggested that the relative shift on idealized humanistic values between the groups in the two samples may have resulted from the differences in age between the samples.

It is interesting to note that Cuban immigrants and Anglo Americans may diverge on many culturally related variables other than nationality. For example, these groups may vary on religious affiliation, child-rearing customs, family structure, and psychological variables such as need for approval, locus of control, and field dependence. The present study did not attempt to control for these variables. To have singled out anyone or a combination of these variables for analyses would have been artificial, since, in fact, these variables and many others contribute to the differences in basic value orientations observed between the two cultural groups examined.

The differences between the two cultural groups may have been caused, however, by variables that are not necessarily culture related. For example, Casavantes (1970) argued that Mexican Americans value the present only as a function of their lower socioeconomic status and not as a cultural value. Since socioeconomic status data were available for the subjects in Sample 2, the Cuban immigrants and Anglo Americans of Sample 2 were compared along this variable, and they were found not to differ significantly. Hence, the findings of the present study do not appear to have been caused by socioeconomic differences as Casavantes would suggest.

Future research should address cultural differences among Cuban subgroups. Differences may exist, for example, between the sexes, among age groups, or between clinical and nonclinical samples. These differences between Cuban subgroups may also have important clinical implications.

Clinical Implications

The differences in basic value orientations between Cuban immigrant and Anglo-American adolescents may have implications for the delivery of mental health services to these populations. If these value orientations are indeed as basic as Kluckhohn and Strodtbeck (1961) postulated, then they must also have

implications for personality and psychosocial development, a notion derived from the work of Papajohn and Spiegel (1971) and Ramirez and Castañeda (1974) among others.

As suggested earlier, clients with specific psychosocial characteristics require treatment approaches matched to their idiosyncratic styles. Following this premise, it would seem that to achieve desired psychotherapeutic outcomes with clinical Cuban populations, it is necessary to identify treatment models that are specifically matched to the culturally determined characteristics arising from the value structure of this population. Therefore, the Cuban adolescents' preference for lineality, subjugation to nature, present time, and doing orientations as well as their low endorsement of idealized humanistic values must be taken into consideration when designing a psychosocial service delivery system for them. Many traditional Anglo-American treatment services are based on a model of a growth-oriented, self-actualizing individual who is ready to take control over his or her own destiny. In contrast, clinical experience at the Spanish Family Guidance Clinic suggests that the provider of psychosocial treatment services to the Cuban immigrant must be ready to take charge of the therapist-client relationship, to validate hierarchical structures in the client's life context, and to intervene on behalf of the client within the client's life context to restore ecological order.

The most important feature of a psychosocial treatment model that is sensitive to the cultural characteristics of the Cuban immigrants is to validate their preference for a lineal style of relationships. This relationship style may receive the support of the therapist in various phases of the treatment. First, the therapist must relate to the client hierarchically, recognizing that the therapist's role is perceived by the client as a position of authority. With this recognition, the therapist assumes responsibility and further takes charge of the therapist-client relationship. Second, the therapist validates the young Cuban client's preference for lineality by enlisting in the treatment process the naturally occurring hierarchical systems in the client's life context. Clearly, the most significant na-

turally occurring hierarchical system is the family. Other authority figures such as teachers, school counselors, and even probation officers may also be important and may need to be included in the therapeutic plan. Many instances of dysfunction in young clients are also accompanied by the breakdown of the lineal structural relational patterns within the family. This is frequently manifested in the young person's open rejection of the parents' executive role in the family. Interestingly enough, even in these instances, clinical experience suggests that desired therapeutic outcomes are reached most expediently by restoring the lineal-hierarchical relational structure in the family. Once the family's natural lineal milieu is restored, and the parents' role as the family's executive system is reaffirmed, then the family is taught the skills necessary to negotiate the youngster's differentiation (transition from lineality to individuality) from the family. The lineal family structure is supported, so that within this basic culturally sanctioned framework, the process of negotiating the youngster's differentiation from the family may take place.

In preparing a psychosocial treatment plan for a Cuban immigrant client, the therapist should also consider the Cuban's sensitivity to environmental social pressures. The high levels of need for approval of Cubans (Tholen, 1974) and field dependence of Latins (Ramirez & Castañeda, 1974) in general have been documented. Because of the strong influence of environmental social pressures on the Cuban client's well-being, it becomes particularly important that the etiology of psychosocial dysfunctions be conceptualized within an ecological framework (Auerswald, 1971), since ecological theory takes into consideration the effects of the interaction between client and psychosocial systems on the client's functioning. Further, as the present study indicates, Cuban clients tend to perceive themselves as unable to control or modify their environmental circumstances (see also Santisteban, 1975). For this reason, when environmental pressures or tensions seem to be a source of client dysfunction, as is frequently the case (Scopetta, King, & Szapocznik, Note 1), it is necessary that therapeutic interventions re-

structure the interactions of the client with his/her environment when these are sources of client functional impairment (Aponte, 1974).

The treatment of the Cuban client must also be present oriented. The Cuban client is usually mobilized for treatment by the onset of a crisis (Scopetta et al., Note 1) and expects the therapist to provide immediate problem-oriented solutions to the crisis situations. In general, the therapist must develop a treatment model that capitalizes on crises to promote personal growth and the reorganization of interpersonal relations. Further, to use maximally this characteristic of the Cuban population, the culturally sensitive therapist is not only cognizant of how to use crises to promote growth but also knows how to create them for the same purpose.

It will be recalled that young Anglo Americans are more likely than Cubans to endorse idealized humanistic values (Factor 2). Since these findings were unexpected, their clinical implications are as yet not clear. Nevertheless, these findings suggest that young Cuban immigrants are less likely than their Anglo-American counterparts to value relationships based on goals of the laterally extended group, and thus to be mobilized in treatment by peer pressure groups. The findings also suggest that young Cuban immigrants are less likely than their Anglo American counterparts to be motivated in treatment by a search for personal and spiritual growth. In fact, clinical experience suggests that the Cubans are motivated in treatment by concrete and obtainable objectives. Consistent with this interpretation, young Cuban immigrants were found to endorse a doing activity orientation, whereas their Anglo American counterparts preferred a being activity orientation.

With recognition of the culturally determined characteristics of the Cuban population, the Spanish Family Guidance Clinic in the Department of Psychiatry of the University of Miami School of Medicine explored a variety of treatment approaches. Among these, one treatment model seemed particularly appropriate, ecological structural family therapy, first proposed by Aponte (1974), who based his treatment model on Auers-

wald's (1971) concepts of ecological therapy and Minuchin's (1974) structural family therapy. The approach of these therapists seems to be particularly appropriate for the treatment of Puerto Ricans (e.g., Minuchin, Montalvo, Guernsey, Rosman, & Schumer, 1967).

Ecological structural family therapy as adopted at the Spanish Family Guidance Clinic is based on therapeutic assumptions that are matched to the value characteristics of the population of Cuban adolescents. Within this approach, the therapist relates hierarchically to the client and works to restore the hierarchical structure in the client's family. The therapist considers the ecological factors impinging on the client and actively intervenes to remediate detrimental ecological relationships based on the notion that the client lacks the orientation to do so unassisted. The therapist is present oriented and intervenes to manipulate existing dysfunctional interactional patterns (cf. Minuchin, 1974) within the family and between the family and its environment. And, finally, consistent with a doing activity orientation, the client is motivated for treatment through the use of concrete and obtainable objectives.

Further studies are under way to test the effectiveness of ecological structural family therapy in the treatment of psychosocial dysfunctions, including drug and alcohol abuse, with a population of Cuban immigrants.

The procedure outlined in this article may have broad implications for the development of culturally specific psychosocial treatment models. It is suggested that this procedure may be applicable to the development of culture specific treatment for other cultural groups. In fact, the VO scale may be used to ascertain basic cultural characteristics in client populations or for specific clients in treatment. Based on the findings obtained with the VO scale, it is then possible to identify treatment features that "match" the individual client or clients population's basic value orientations.

Personality Characteristics of Long-Term Recovered Alcoholics: A Comparative Analysis

William M. Kurtines, Leah R. Ball, and Gloria H. Wood
Florida International University

This study reports data on the personality characteristics of alcoholics in two stages of recovery (short and long term). Three samples (total $N = 183$) were used in this study: (a) 60 newly recovered alcoholics (30 males and 30 females with at least 3 weeks but less than 4 months of sobriety); (b) 62 long-term recovered alcoholics (31 males and 31 females with a minimum of 4 years of continuous sobriety and a mean length of sobriety of 8.9 years); and (c) 61 nonalcoholic controls (30 males and 31 females who reported moderate to infrequent or no use of alcohol). All subjects were administered the California Psychological Inventory and a biographical data sheet. A multivariate analysis of variance was used to test the significance of group differences on the personality variables, and a multiple discriminant analysis was conducted to determine the most discriminating dimensions for differentiating among the three groups. The results of the analysis clearly indicate the existence of differential patterns of psychological adjustment at each stage of recovery.

Early research on the personality characteristics of alcoholics focused on the identification of a single alcoholic personality type. The results of this research effort were generally disappointing (Sutherland, Schroeder, & Tordella, 1950; Syme, 1957), and the need for alternative conceptualizations are obvious. Recent research studies have tended to focus on the identification and classification of personality patterns common to alcoholics (Goldstein & Linden, 1969; Lawlis & Rubin, 1971; Nerviano, 1976; Nerviano & Gross,

1973; Partington & Johnson, 1969; Skinner, Jackson, & Hoffman, 1974; Whitelock, Patrick, & Overall, 1971), and the results have led to a more realistic reappraisal of alcoholics as a heterogeneous treatment population (Nerviano, 1976). In general, these studies have used multivariate data analysis procedures to identify distinctive personality profiles among newly recovered alcoholics or alcoholic patients undergoing treatment. Skinner et al. (1974), for example, used a multivariate classification strategy and the Differential Personality Inventory (DPI; Jackson & Messick, 1970) to identify eight modal personality profiles among male alcoholic psychiatric patients. A more recent study by Nerviano (1976), using the Personality Research Form (PRF; Jackson, 1967), used a multivariate approach to identify seven common personality patterns among male alcoholics undergoing treatment in a Veterans Administration hospital.

Overall, considering the variety of assessment devices and methodological approaches used in these studies, there has been a remarkable convergence of results. Skinner, Reed, and Jackson (1976), for instance, have

The authors would like to express appreciation to Wayne F. Cascio, Harrison G. Gough, Dennis Murphy, and Vincent J. Nerviano for their helpful comments on an earlier draft of this paper. We would also like to thank the following individuals for their kind assistance in the gathering of the data: David Altschuler, Director Residential Services, Comprehensive Alcohol Program, Dade County, Florida; Ross A. Garnsey, Director and Founder, Bethesda Manor, Catholic Service Bureau, Dade County, Florida; and Lester Bashara for the use of the facilities of the Miami Church of Religious Science.

demonstrated the feasibility of generalizing the modal personality profiles derived from alcoholics (cf. Skinner et al., 1974) to other psychiatric samples. Moreover, Skinner et al. (1976) observed that two particular profiles (Type I: defensive-repressive, and Type II: impulsive-socially deviant) were notably pervasive across all of the samples used in their study, a finding that is strikingly consistent with those reported by Nerviano (1976). The two most frequently occurring personality patterns in the sample of alcoholics used by Nerviano (1976) were Type A (high impulse control, low autonomy) and Type B (extremely low impulse control).

In view of the substantial body of research currently available on the personality patterns of alcoholics in the initial stages of recovery, it is surprising to find that to date, little research has been conducted with long-term recovered alcoholics. There are, for example, no readily available studies on the personality characteristics of these individuals. The paucity of research on long-term recovered alcoholics is particularly striking in light of the generally acknowledged difficulty in working with alcoholics as a treatment population (Huber & Danahy, 1975; Tamerin & Neumann, 1974). The lack of research in this area may be due, in part, to the difficulty in obtaining data on such persons. Long-term recovered alcoholics are not typically identified with treatment programs and consequently are not readily available to the interested researcher. Moreover, because of the social, personal, and occupational stigma associated with alcoholism, the recovered alcoholic usually seeks to preserve anonymity. Thus, although the research literature contains valuable information about the personality characteristics of newly recovered alcoholics, there is a conspicuous lack of data on the characteristics of individuals who have been able to maintain long-term sobriety. Such data would provide useful clinical information concerning the specific types of personality characteristics associated with long-term recovery among alcoholics as a treatment population.

The purpose of this study was to identify differential personality characteristics associated with both short- and long-term recovery
